Once culture supplanted inheritance as an explanation for degeneracy, removing essentialist justifications for discrimination against stigmatized groups, the general public needed an explanation/justification for why the selfsame public was so unjust and segregationist (Jackson, 2001), and hence came in the study of prejudice. Before the concept was 'operationally defined,' prejudice was not typically viewed as a social problem or even a scientific construct for that matter; instead, negative intergroup attitudes were generally seen as natural and inevitable responses to group differences. This monumental change in the research agenda on stigmatized groups provided researchers and the general public a logical explanation for why there was so much antipathy, and the social scientific attention turned away from the 'miserable' lives of stigmatized individuals and onto the perpetrators of prejudice who made the stigmatized so 'miserable.'

Allport's Theory of the Nature of Prejudice

As the shock of WWII was settling in and societal and academic focus turned toward explaining and obliterating anti-Semitism, racism, and segregation, Gordon Allport's (1954) *The Nature of Prejudice* offered a unifying social psychological explanation of these processes. Although focused more narrowly on racism and ethnocentrism at the expense of attention to many other forms of prejudice, Allport made four significant contributions to the understanding of stigmatization with his comprehensively unmatched theory. First, he provided an integrated sociological and psychological framework for understanding stigmatization. Second, he did not restrict his analysis to only one stigmatized group, as in past research, but instead synthesized research on general stigmatization processes, regardless of which social groups were the target. Third, he integrated research on both dominant groups and stigmatized groups – focusing on the perpetrations of the former and the responses of the latter – a rarity in a body of literature that to this day tends to focus exclusively on only one or other. Gladden's 'social gospel' and Boaz's concepts of 'culture' were quite evident in Allport's chapter entitled "Discussion of Traits Due to Victimization" about the character of people who are subject to stigmatization: "One's reputation, whether false or true, cannot be hammered, hammered, hammered, into one's head without doing something to one's character" (p. 142). Allport's fourth contribution was his multidimensional model of stigmatizing factors that recognized stigma to be a layered phenomenon. He offered an elaborate sociological model that presages current research on nearly every level of analysis in the social structure of prejudice and stigmatization: history, sociocultural influences, situational factors, personality differences, phenomenological (social cognitions), and the traits of the target. Contemporaries of Allport in sociology followed a similar view of stereotyping as resulting from cognitive biases, bad social policy, and miseducation, rather than from instinct or direct animosity. Allport's model could accommodate a wide range of intergroup theories including scapegoat theory, social dominance theory, authoritarianism, realistic conflict theory, self-fulfilling prophecy, and social identity theory (Tajfel and Turner, 1979). Allport's (1954) model suggests that these may be 'normal' processes, but at the same time malleable from a social engineering perspective. In a concluding section of the book, he discusses the success of social change programs and asks prophetically in a chapter title "Ought there to be a law?" (p. 461). The

response of impatient social scientists, as noted by Jackson (2001) was to build "an argument that it was not necessary to wait and do nothing while society 'evolved' more egalitarian" (p. 9). Social scientific attention to unfair treatment of and attitudes toward stigmatized people has continued well into the twenty-first century (Falk, 2001).

Goffman's Stigma and the Spoiled Interaction

Just after Allport redirected the social science of stigma onto prejudice and the prejudicial, Erving Goffman brought the focus right back to stigma and stigmatized people in his 1963 book *Stigma: Notes on the Management of Spoiled Identity*. This was the first social psychological synthesis of stigma research in the twentieth century, discussing an array of stigmatized groups. Using a symbolic interactionist framework, Goffman characterized stigma as a situation in which a devalued attribute of an individual jeopardizes acceptance from others who anticipate a usual, expected, or 'standard' person but instead are faced with an unusual, unexpected, or discounted one. Goffman emphasized the interactional nature of interpersonal encounters between stigmatized and nonstigmatized individuals, including an analysis of ways in which stigmatized people cope with their situation. Goffman (1963) described three general types of stigma: bodily 'abominations' (e.g., physical irregularities), blemishes of individual character (e.g., criminal behavior), or tribal stigma (e.g., ethnicity). A person with a stigma may be viewed as abnormal due to their possession of a 'shortcoming' and thus be subject to either deliberate or unintentional marginalization and oppression including prejudice, stereotyping, and discrimination. Further emphasizing the relational nature of stigma, Goffman distinguished two types of stigma, the discredited (who are already known by others to have a stigmatizing trait) and the discreditable (who have the trait, but others may not already know).

There has been no other treatment of the subject of stigma that parallels Goffman's approach to categorizing and classifying the nature and types of stigma, excepting Jones and colleagues' (1984) *Social Stigma: The Psychology of Marked Relationships* published 20 years later. Jones and colleagues described six dimensions of stigma that expand upon Goffman's discredited/discreditable dichotomy, adding concealability of the stigmatizing attribute, course (duration and permanence) of the stigmatizing attribute, disruptiveness of the stigmatizing attribute in social interactions, aesthetic qualities of the stigmatizing trait, origin or cause of the stigmatizing trait, and perilousness of the stigmatizing trait to others. Together, these works ensured that research on the experiences of stigmatized people would continue; unfortunately, traces of the perspectives of eugenicists, race theorists, and the social gospel remained. Several of Goffman's source materials were products of these earlier agendas that preceded him and much of his terminology would be deemed overtly degrading by modern standards (e.g., contrasting 'stigmatized' 'cripples,' 'illiterates,' and 'very Orthodox Jews' with 'normals'). Goffman criticized stigmatized individuals who "flaunt their refusal to accept their place" (p. 145) and described coping in patronizing tones as in "the tortured performance… when an individual confined to a wheelchair manages to take the dance floor with a girl in some kind of mimicry of dancing" (p. 10). He described 'defiant' stigmatized individuals as those who have the audacity to think of themselves as 'normal.' He also roused old themes of depraved culture in his description of the culture of deviant elements in society:

> Prostitutes, drug addicts, delinquents, criminals, jazz musicians, bohemians, gypsies, carnival workers, hobos, winos, show people, full time gamblers, beach dwellers, homosexuals, and the urban unrepentant poor… failing to use available opportunity for advancement in the various approved runways of society…show open disrespect for their betters; they lack piety; they represent failures in the motivational schemes of society. (p. 171)

Some of these early themes of deviance continue to haunt the public's views. For instance, people are more supportive of stigmatizing people whose status is seen as uncontrollable/ascribed rather than controllable/achieved, and stigmatized group members make difficult choices about concealing, passing, or revealing the origins of their stigma. Goffman implied that the responsibility to ease the problems of stigma lies with stigmatized individuals not with 'normals' because "normals really mean no harm; they don't know better" (p. 116). Reflected in contemporary psychological work that favors individualistic sociocognitive coping over group solidarity and activism, Goffman saw 'good adjustment' as in the hands of the stigmatized:

> It requires that the stigmatized individual cheerfully and unselfconsciously accept himself…voluntarily withholds himself from those situations in which normals would find it difficult…it means that normals can remain relatively uncontaminated by intimate contact with the stigmatized, relatively unthreatened in their identity beliefs. (p. 121)

Goffman laments, that although this means taking on all this responsibility for society's weakness, this strategy promises "the best return he can get on his money" (p. 122).

Goffman's version of the social gospel guaranteed that in the second half of the century researchers would continue to wrestle with the idea that the possession of stigma is universally burdensome. His fatalistic view of stigma reinforced self-hate themes even as integration and upward social mobility meant that many stigmatized individuals were gaining in status. Research turned to characterizing stigmatized individuals in intergroup settings as being hassled, vigilant, distracted, and tokenized. Indeed, even Goffman recognized that context is key, although his obsession with the demoralizing treatment of stigma assumes a backdrop of a 'mainstream' 'normal' cultural context. Goffman cautions that all people have experience negotiating stigma from both sides, because we all possess attributes that in some contexts can be stigmatizing. The individual, contextual, and cultural relevance of any stigmatizing attribute fluctuates (Campbell and Deacon, 2006). There are even contexts in which culturally valued social groups can experience stigmatization due to 'positive deviance' and the 'model minority stereotype.'

Influence of the Civil Rights Movement

The cultural context began to change dramatically throughout the civil rights movement, and researchers had to disentangle

the erroneous confounding of stigmatized identity with intellectual inferiority, mental illness, and low self-esteem (Crocker et al., 1998; Cross, 1991). The conclusion that self-hatred is inevitable and only artificially correctable has been questioned by findings that members of stigmatized groups typically have high self-esteem. The work on stigma moved into a new phase in view of new cultural norms, new rights, higher social standing, celebration of group pride, and a rising number of minority scholars who changed not only how members of stigmatized groups were perceived in society, but also how they were portrayed in academia. The old idea that marginalized groups are immoral and their damaged culture pathological was replaced with a reclaiming of culture of as "valuable and worth preserving" (Jackson, 2001: p. 3).

During this time, complex and affirmative theories of self-concept emerged acknowledging the within-group variability in the group identities of members of stigmatized social groups, including identities that are politicized and empowering. Group identity has been shown to be positively associated with well-being, motivation, resilience, performance, self-protection, and willingness to stand up to social injustice. Research has revealed a diverse and multifaceted concept of group identity that has universal and group specific characteristics, is flexible to changes throughout the life span and across situations, and may be both empowering as well as challenging to achieve and sustain, especially for groups who are highly stigmatized or geographically isolated.

Contemporary Levels of Analysis

Social psychologist Thomas Pettigrew has noted how psychologists "rarely combine levels of analysis in order to put individual and situational phenomena in their macro-contexts" (Pettigrew, 2010: p. 615). Allport's (1954) exhaustive theory was rare in its attention to the individual and intergroup levels, as well as sociocultural and historical perspectives. Research on stigma combining all its multileveled complexity has proved to be a significant challenge for researchers. As one's focus is crisply positioned at one level, there is another level that is made fuzzy.

Stigma at the Individual Level

At the turn of the twenty-first century, a focus on stigma from the *Target's Perspective* contributed to the understanding of stigma in two major ways (Swim and Stangor, 1998). First, the *Target's Perspective* prioritized the insider's perceptions on their daily lives with qualitative reporting of their experiences by and for a diversifying group of academics. Concepts of 'everyday prejudice' and 'microaggressions' emerged to characterize the mundane experiences with prejudice in daily living. This approach represented a marked change from Allport, Goffman, and their contemporaries who had (with some exceptions) been writing secondhand about stigma to a nonstigmatized audience. Thus, the *Target's Perspective* made it possible for stigmatized individuals to represent their daily experiences in their own words in the scientific literature. This writing improved the language and assumptions made in past social scientific work and revealed some unexpected results, such as the reserve stigmatized group members exercise when perceiving and responding to disadvantage. Second, the *Target's Perspective* benefited from the opportune timing of its emergence post-Allport and post-Goffman, which afforded researchers the ability to move from the contextualized experiences of a single stigmatized group to a larger general theory of prejudice and stigma, and vice-versa. The localized study of certain stigmatized groups' experiences from the insiders' voice became valuable in its own right, and at the same time essential to developing the larger theory of stigma and prejudice in society. There is now a more empowering view of stigmatized individuals, not as victims constrained by a predetermined set of inferior life outcomes, but as active copers adjusting strategies to meet individual and situational needs. Individual differences in how stigmatized people cope have been given new attention. *Target's Perspective* research that explores 'confrontation' over 'coping' has revealed that targets have a well-developed repertoire to draw from in acts of interpersonal resistance (Hyers, 2010). Shih (2004) has argued that the most resilient in the battle against stigma are those who adopt 'empowerment' strategies rather than framing their efforts merely as 'coping' with the stigma they face.

When focusing on stigma from the *Target's Perspective*, two major limitations become apparent. First, it could be misinterpreted as implying that the responsibility for correcting oppressive social stratification lies solely in hands of stigmatized people without also addressing sociostructural inequalities (Hyers, 2010). Second, it may falsely represent stigmatized groups as orthogonal and one-dimensional (as if people in the category 'lesbian' do not have an ethnicity, people in the category 'African-American' do not have a gender, etc.). Theorists coming out of gender and ethnic studies traditions offer a range of metaphors for the complex ways in which stigmatization and identity manifest at the individual level. Crenshaw's (1991) influential intersectionality theory emphasizes that all people are multidimensional, group memberships are not orthogonal once embodied, stigmatizing forces intersect in unique ways, and when people possess multiple group memberships (e.g., lesbian women of color with disabilities), these dimensions cannot be easily separated for analysis. This problematizes discussions of singular prejudice or measures of one-group identity, since experiences and identity are shaped by a combination of factors such as race/ethnicity, social class, gender, income/socioeconomic status, and disability status. Research comparing the experiences of two stigmatized groups (e.g., lesbians being compared to people with disabilities) implies that the groups are mutually exclusive, neglecting the 'double' and 'triple jeopardy' of multiple stigmas. Stigmatizing attributes are not simply additive; for example, there is not just racism and sexism, but also gendered racism, and gendered racism may be further impacted by socioeconomic status.

Stigma at the Interpersonal/Intergroup Level

Allport's (1954) attention to the intergroup situation along with Kurt Lewin's work on group dynamics encouraged research on intergroup contact that has grown quite prominent in the psychological research on stigma, especially

with regard to identifying and enhancing the intergroup processes that lead to internal cognitive and emotional change. According to social identity theory, individual identity is shaped by group memberships; therefore, individuals engage in strategies that elevate the status of their groups (Tajfel and Turner, 1979). Expanding upon Allport's (1954) distinction between intropunitive actions aimed at adapting to others and extropunitive actions aimed at blaming outside forces, social identity theory proposes three strategies: social 'creativity' (valuing one's in-group), individual mobility (striving to leave one's stigmatized status), and social competition (action against injustices). This work has been flexible enough to be relevant to work on stigma and stigmatization, perpetrators and targets, and prejudice formation and reduction. Intergroup research has been criticized for its use of artificial laboratory settings, minimal groups design, and experimentally created and randomly assigned 'stigmas.' A second criticism is in regard to the negative light that has been cast on intergroup encounters, especially with regard to the stigmatized participants, since research shows that both stigmatized and nonstigmatized individuals exhibit intergroup anxiety and avoidance coping. A third criticism is in regard to the promotion of the strategies of the common in-group identity model and 'colorblindness,' which contradict other work at the individual level on the importance of contextualized identity (e.g., intersectionality theory). Intergroup research that focuses on group-honoring intergroup processes, such as appreciating difference and self-reflection, may fit more nicely with perspectives on stigma embodied and *Target's Perspective* research on the 'educational moment' in dynamic exchanges when stigmatized individuals confront others. Regretfully, similar to the *Target's Perspective* research, interpersonal/intergroup research has not given enough attention to the dynamic exchange of actions and interactions of both players in the immediate intergroup context.

Stigma at the Macrosocial Level

Research and intervention on stigma directed at the societal level complements the previous two levels of analysis. As Steele et al. (2002) note, stigma does not reside in the person "but in the unfortunate circumstance of possessing an attribute that, in a given social context, leads to devaluation" (p. 506). In other words, a stigmatizing attribute is possessed by an individual, but defined by larger social and cultural constructions of power. The field of psychology tends to direct the focus away from vast macrosocial forces including economic, political, and social unrest; institutional discrimination; global geopolitical power dynamics; and historical inequities. Research on interdependence and power shows that power impacts not only how prejudice is expressed, but also how one perceives and responds to it. Coping with one stigmatizing attribute (e.g., disease, poverty, and criminal status) is affected by the possession of other hierarchically organized identities (e.g., skin color, nationality, and sexual orientation) and the impact of existing cultural institutions (e.g., hospitals, schools, churches, and marriage rites). Stigma has been most promisingly addressed in educational institutions and workplace settings.

New Directions

Addressing the Subtlety of Stigma

The response of the public to stigma has changed since the civil rights movement, and so, too, has the approach of social science. *De facto* stigmatization is illegal yet *de jure* stigmatization remains, making it harder for the public to understand, victims to identify, the legal system to prosecute, and for researchers to study. Nier and Gaertner (2012) dedicated a special volume of the *Journal of Social Issues* to "The Challenges of Detecting Contemporary Forms of Discrimination." The shift toward the subtle is reflected in modern, symbolic, aversive, ambivalent, and benevolent prejudice theories and in work on dominant group privilege, entitlements, and conferred dominance. Stereotype threat research similarly suggests that situational threat can be quite subtle. Research methods and measures have grown more discrete using subtle measures of implicit associations, response latency, heart rate, eye blinks, functional magnetic resonance imaging, and delayed memory deficits. Even *Target's Perspective* research, with its focus on the personal narrative and voice of stigmatized individuals, recognizes that chronic, subtle, everyday prejudice can be intentionally or unintentionally forgotten or dismissed, ergo the use of daily diaries, experience sampling, checklists, palm pilots, and photo diaries to document the subtle but accumulating stigmatization.

Stigmatized Groups in Focus in the Early Twenty-First Century

Link and Phelan (2001) remind us that the concern about stigma is first and foremost a concern over unfair limits placed upon human chances for health, economic security, housing, and education, as well as psychological well-being. As has been the case throughout the history of academic work on stigma, contemporary social problems shape the discourse and research agenda. Several stigmatized groups facing pressing injustices have been accorded more intensive focus of late.

Stigma of Poverty

Early Race Theorists had described poverty as a moral failing resulting from the intergenerationally transmitted deviant 'culture of poverty.' For decades, psychologists interested in prejudice still left concerns over the stigma of poverty to sociologists and economists, because social class was not seen as a psychological identity, per se. With income inequality increasing in the United States and globally, the American Psychological Association finally established a Task Force on Socioeconomic Status in 2007. International commerce has intricately tied the socioeconomic statuses of people in cultures around the globe. In the increasingly connected international labor force, the stigma of relative poverty is as relevant as the stigma of absolute poverty. Ironically, race theories from the past continue to resurface, some actually suggesting that stigma and shame are functional because they motivate the otherwise "indolent masses" to strive (Murray, 2012).

Stigma of Aging

Another rising stigmatized group that has been calling for more attention is the aging population. Entrenched institutionalized ageism and derogatory cultural stereotypes of aging are occurring at a time when cosmetic and medical advances to 'turn back

the clock' are booming, and populations are living longer. With a disproportionate aging population in many parts of the world where aging is viewed negatively, the stigma of aging is coming to the fore.

Stigma of Disability

Goffman's writing on disability was some of the most offensive, especially when he described disability as a situational 'failing' of the stigmatized person for not being the 'normal' person others expected. In dramatic contrast, a major social shift propelled by disability activism emphasizes that in fact, the person making normality assumptions has 'failed.' This represents a new standard in which people in all contexts must anticipate and accommodate all variations of human competencies. Standards of the Americans with Disabilities Act compliance, ecological design, the social (and the radical antisocial) models of disability, and even demand for 'safe spaces' have changed the playing field dramatically since Goffman. After decades of efforts by the mental patients' rights movement, the World Psychiatry Association established guidelines for reducing the stigma of mental illness in 2010. This effort is further strengthened by new attention to war veterans and first responders who may face disability, trauma, and social isolation, but feel inhibited from asking for help.

Future Frontiers

The last century has brought substantial progress to the research and realities of stigma in our culture; however, there is more work ahead (Barreto and Ellemers, 2010). From a global perspective, the progress of Western Psychology has not crossed boundaries as much as it should. Stigma remains critically divisive to the social order within and across many cultures, in the relationships between 'fourth world' indigenous and 'first world' colonizing nations, and in the struggles of immigrants and refugees around the globe. Furthermore, in the virtual world of cyberspace, there is a new unregulated domain wherein stigmatization has been transferred from the real world and sometimes back again in the form of 'cyber bullying.' Interestingly, a number of 'antibullying' and 'allies' programs have developed into widespread and unified responses to extreme incidents of cyber bulling. Stigma research also has the potential to make major contributions to environmental protection. There are obvious parallels between humans' stratification of each other and their stratification of nonhuman animals and the environment – differentiating, collecting, classifying, labeling as primitive, exoticizing, and thereby legitimizing exploitation (Swim et al., 2009). As the understanding of and sensitivity toward stigmatization continues to grow, one can hope to see increasingly more successful collaborations between activists and applied science scientists in the years to come.

Stochastic Models

David J Bartholomew, London School of Economics and Political Science, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Human behavior is, to some degree, unpredictable. The description and prediction of social systems therefore requires models of such systems to be stochastic. Most social systems can be described at any time by the numbers of people in various categories. Change over time is described by probabilities and these enable one to trace the trajectory of the system over time using the theory of stochastic processes. This article describes some of the basic models that have been widely used for such systems and suggests that the way forward depends mainly on constructing realistic simulation models of real-life systems.

Terminology and Background

The term stochastic model is used in a broad sense and a narrow sense in the social sciences and beyond. In the broad sense, it refers to any model involving probability and thus includes, for example, the standard regression model and random sampling from finite populations. In the narrow sense, it refers to models for social systems and it is in that sense that it is used here.

The characteristic feature of such a model is that it involves the unpredictable behavior of a collection of people. It attempts to describe the behavior of such a system, usually over time. Its starting point is with individuals who behave unpredictably, to some extent, and then it seeks to deduce the aggregate properties of the system. It is an empirical fact that the behavior of individuals varies. In making purchases in a supermarket, for example, individuals will choose different brands, apparently haphazardly and in voting in an election they will back different candidates. In a purely deterministic world, every such action and choice would be determined, and in principle at least, the future would then be entirely predictable. The reality is quite different.

Individual unpredictability has no particular philosophical implications. It does not imply, for example, that decisions are made as if by the toss of a coin. It could be, of course, that each of us is a random automaton with some neural randomizer that determines our every thought and action but that is not necessary. As a matter of fact, choice does mimic chance and patterns of choice can often be well described by probability distributions. In technical language, the element of chance in our models is not ontological but epistemic.

The rapid growth in the power of computers in the last few decades has radically changed the context in which stochastic modeling takes place. In order to delineate this change, it is useful to see the field as consisting of two parts. First, there is the construction of stochastic models and second, their analysis. It is on the analysis that computing has had the greatest effect. Models that formerly would be regarded as involving too much heavy computation have now come within the realm of the possible. This might be seen as a source of encouragement to construct ever more complicated models. But on the construction side, the effect has been much more subtle. The limiting factor there is no longer the amount of computing power available but the capacity of the analyst's mind to encompass the results of the exercise. The mere proliferation of models in number and complexity achieves little unless it provides insight into the fundamental character of the processes being modeled. The prime purpose of a stochastic model is to obtain a firmer intellectual grip on the reality underlying the process studied. The strategy in this article is, therefore, to focus on simpler models which, although may not always be fully realistic, give genuine insight into the reality that the model is designed to capture.

Uncertainty in human behavior is not confined to the social sciences as commonly understood, of course, but it occurs also in many contiguous areas. Population genetics and epidemiology are two examples and some of the models mentioned had their origins in these fields. Nevertheless, there is a unity in models used in the social sciences, which justifies their being treated as a coherent whole.

In this article, the author traces a progression from the simple to the complex. Beginning with an example simple enough to easily comprehend and yet being capable of displaying some of the subtlety of more complex models, the author goes on to develop the ideas in larger and more realistic examples.

A Simple Example (The Poisson Model)

The simplest of all probability models stems from the idea behind coin tossing. If a coin is tossed independently and repeatedly, one observes a succession of heads and tails in roughly equal numbers but in no particular order. It is a straightforward extension of this model to suppose that the chances of heads and tails are not equal and to note in particular, that there is nothing to prevent the probability of heads being very small. There are, in fact, many situations in which human choice making shows these characteristics. For example, the chance that any individual meets a long-lost friend on any particular day may be very small indeed, but in the course of a year they may meet several. The actual number is uncertain and that number will have a probability distribution. It is a remarkable fact that the probability distribution of this number often closely follows what is

known as a Poisson distribution. The probabilities do not even have to be equal but providing they are all very small and the number of occasions is large, the probability of observing exactly n occurrences will be

$$P(n) = m^n/_{n!} \exp(-m) \qquad [1]$$

where m is the mean number of occurrences and n can take any nonnegative integer value. This is a natural place to start since it makes minimal assumptions about behavior. In practice, however, it often fails to represent the pattern of variation adequately. For this reason, it is sometimes referred to as a baseline model as it forms the starting point for a deeper investigation. One useful property of the Poisson distribution is that its mean and variance are equal. A quick check on the adequacy of the fit of any distribution is therefore to compare the mean and variance. It is often found that the observed distribution is 'overdispersed' meaning that there is more variation than one would expect on the Poisson hypothesis. An important function of modeling is to try to explain this departure by generalizing the model.

There are many possible generalizations. The most natural, perhaps, is to relax the assumption that all individuals experience the same risk. The parameter m may be thought of as a measure of risk because it is the mean number of accidents per unit time. One could suppose that there were two risk groups present – a high-risk group and a low-risk group. The observed distribution would then be a mixture of two Poisson distributions one with parameter m_1, say, and the other with m_2. Alternatively, the sample might have come from some larger population in which risk varied continuously. A common assumption is that m varies continuously according to a gamma distribution whose density function may be written

$$h(m) = \frac{c^q}{\Gamma(q)} m^{q-1} e^{-cm}. \qquad [2]$$

The resulting distribution of counts is then

$$P(n) = \binom{n+q-1}{q-1} \left(\frac{1}{c+1}\right)^n \left(\frac{c}{c+1}\right)^q \qquad [3]$$

This is known as the negative binomial distribution because its successive terms can be generated by the expansion of a binomial expression with negative index. It is easy to show that its variance is greater than its mean, as anticipated.

There are many other possible generalizations. It may be that individuals do not differ, but instead, that successive accidents are not independent. For example, it could be that having one accident makes one more liable to have another. Neyman proposed what are called 'contagious' distributions, which embody this feature. If accidents tended to cluster, there would be relatively more periods with more accidents than expected and others with fewer, since the mean is fixed. Qualitatively, this has a very similar effect to mixing.

These examples illustrate how successively more complicated models may help to identify new features and, more importantly, perhaps, demonstrate the limits of modeling. An important aspect of this is the indistinguishability of quite different models for the same phenomena.

Time has played no explicit role in the models so far. Accidents do occur in time, of course, but the mere passage of time was supposed to play no part. Most of the models to be discussed in this article develop over time, and time itself is an important factor in determining what happens.

One can introduce time into the simple coin tossing model by supposing that tosses take place at unit intervals of time. One then looks at the intervals between successive 'heads.' For a head to occur at the nth toss after the last one, there must be $n - 1$ tails in succession followed by a head. The probability of a head thus has probability $(1-p)^{n-1}p$. If n is the interval length, the probability distribution of n is therefore

$$P(n) = (1-p)^{n-1}p, \ldots n = 1, 2, \ldots \qquad [4]$$

This is the geometric distribution. The random variable n now represents the time before a head first occurs. One speaks of this as a discrete time model.

Suppose one imagines the time interval between tosses becomes very small, of length δt. On the new scale of measurement, the time interval between heads will be $t = n\delta t$. If one were to leave p unchanged, the interval between heads would become very short. To compensate for this, one needs to allow the probability to become small at a rate that exactly balances the increased rate of tossing. Thus, suppose $p = \lambda\delta t$, then

$$\Pr\{\text{head occurs in } (t, t+\delta t)\} = .\lambda\delta t \exp(t/\delta t - 1)\text{In}(1 - \lambda\delta t) \qquad [5]$$

As $\delta t \to 0$ this approaches

$$\lambda e^{-t}\delta t. \qquad [6]$$

The probability $p = \lambda\delta t$ may now be called an infinitesimal probability, λ the rate of occurrence, and $f(t) = \lambda e^{-\lambda t}$ the probability density function of the time interval.

This link between the discrete time version of a model and its continuous time counterpart arises frequently in stochastic modeling and one shall meet it again in connection with Markov models below.

As with the Poisson distribution, the very simple assumptions on which the waiting time distribution depends are seldom met in practice but provide a good baseline model from which more realistic models may be derived.

Accounting Equations

A very large number of social systems have the following structure. People are distributed over a number of categories. Over time, individuals move from one category to another, or leave the system altogether. If these moves are, in some degree, unpredictable, one needs a stochastic model to describe the development of the system. The starting point for almost all models is a set of accounting equations connecting the stocks and the flows. The numbers in the categories at any time are the stocks and the number in category i at time T is denoted by $n_j(T)$. Similarly, the number moving from i to j in the interval from $T-1$ to T may be denoted by $n_{ji}(T-1,T)$ and these are the flows. If $i = j$, this is the

number that does not move. All internal movements are then accounted for by the equations

$$n_j(T+1) = \sum_{j=0}^{k} n_{ji}(T, T+1) \qquad [7]$$

where k is the number of categories and i runs from 1 to k. Movements into the system from outside may be covered by letting the subscript 0 denote the outside world. Losses in the interval are not in the system at time T and therefore do not appear in eqn [7]. Any stochastic model of the system will have to specify the process of change.

In a Markov model, it is assumed that the probability that an individual moves from i to j in any interval depends only on the origin state and that that all such moves are independent. At first sight, the requirement for the probability to depend only on the current state seems very restrictive but, as seen later, this difficulty can be considerably ameliorated by an appropriate definition of the states.

Markov Models

The Discrete Time Closed Model

Three kinds of Markov models are described but they all have one thing in common, which justifies the terminology. This is the set of transition probabilities between states, which may be set out as follows.

$$\begin{pmatrix} p_{11} & p_{12} \cdots \cdots \cdots & p_{1k} \\ p_{21} & p_{22} \cdots \cdots \cdots & p_{2k} \\ p_{k1} & p_{32} \cdots \cdots \cdots & p_{3k} \end{pmatrix} \qquad [8]$$

where p_{ij} is the probability of moving from state i to state j at any stage. In practice, some of the elements may be zero as when the states form a hierarchy of some kind in which downward movement is impossible. If the system is closed, so that no one enters or leaves, the row sums will all be unity. Such a system is 'closed' and the existing theory of Markov chains can be applied with little modification.

Totally closed systems are quite rare in practice but they may be a reasonable approximation especially when any replacements are equivalent to those that have been lost (see also the third type of Markov model discussed below where the correspondence is exact).

The development of a Markov chain over time can be traced by means of the expected numbers in the categories. Thus, let $n_i(T+1)$ denote the number of individuals in state i at time $T+1$. These numbers may be collected into a row vector $n(T+1)$. To calculate the expectation of $n(1)$ given $n(0)$, say, one must enumerate all the paths from each state at time 0 to each state at time 1 and compute their expectations. For example, state j can be reached at time 1 in one step from state i at time 0 and the probability that this happens, conditional on being in state 0 initially, is p_{ji} and hence the expected number in state i is $n_i(0)p_{ji}$ or, in matrix notation,

$$n(1) = n(0)P$$

where $\boldsymbol{P}$ is the transition matrix defined above. Repeated application of this argument for successive points in time gives

$$n(T+1) = n(0)P^{T+1}.$$

It follows at once that the elements of P^{T+1} give the probabilities of going from state i to state j in $T+1$ steps. These are known as the $(T+1)$ step probabilities and are sometimes written

$$p_{il}^{(T+1)}.$$

There are two state vectors that are of particular interest. These are the 'limiting' vector, if it exists, and the 'stationary' vector. If one follows the system for extended periods of time, the state vector might settle down to a limiting value or it might vary indefinitely. The former situation applies under certain conditions, which amount, roughly speaking, to saying that it must be possible to reach any state from any other state. In that case, a limiting state vector exists. It may be found empirically by repeated powering of the transition matrix, or by other means, but it turns out that P^{∞} has identical rows, which may easily be deduced from eqn [9] below.

The second state vector of particular interest is the stationary vector. A vector is stationary if it is unchanged by the transition process. That is, it must satisfy

$$n = n\,P. \qquad [9]$$

This stationary vector turns out to be identical to the limiting vector.

In practice, the Markov model is often used to predict the numbers of individuals who will be in the categories at different times in the future. Thus, if initially there are N people distributed across the categories according to $\boldsymbol{n}(0)$, the expected numbers in the categories at time T will be given by $n(T)$. Similarly, numbers in the categories in the limiting, or stationary, state will be n. The stationary state is of particular interest in many applications because it represents the stable structure that can be maintained indefinitely. Any other state distribution cannot be maintained under the operation of the given transition matrix.

The foregoing theory is concerned only with expected values. It is easily possible to find recurrence relations from which the variances, covariances, and higher moments of the category sizes may be determined. These will be found, for example, in Bartholomew (1982: pp. 20ff).

Open Markov Systems with Fixed Input

Many systems, such as, for example, educational systems, are fed by a constant flow of new entrants. This total number may vary over time but, in order to concentrate on the principle of the matter, it is assumed to be a fixed number, R, say. Suppose that these are allocated to categories with probabilities $\{r_{\downarrow}i\}$. The expected flow into category i, which is denoted by $n_{0i}\,(T-1, T)$ in eqn [7] will then be Rr_i. Taking expectations on both sides of eqn [7] and assuming that internal movements are governed by the transition matrix $\boldsymbol{P}$, one then finds

$$n(T+1) = n(T)P + R\boldsymbol{r}. \qquad [10]$$

If there were no losses, the size of the system would grow without limit, but otherwise, the structure will approach a limiting value satisfying

$$n = nP + Rr_i \qquad [11]$$

or

$$n = Rr(I - P)^{-1} \qquad [12]$$

where the existence of the inverse is guaranteed by the fact that some, at least, of the row sums of $\boldsymbol{P}$ must be strictly less than one.

Open Markov Systems with Fixed Size

There are many fields where there are constraints on the size of the whole system or, even, on the size of individual categories. Manpower systems are a good example. In such cases, the model needs to be modified and this is easily done when it is the overall size that is fixed. All that one needs to do is to ensure that the total input matches the total loss. For this purpose, a symbol is needed to denote the probability of leaving state i, which is obviously one minus the total probability of moving elsewhere in the system. It is convenient and natural to denote this by p_{i0}. The expected number of leavers between T and $T+1$ is then $n(T)p_0'$ where p_0' is the column vector with elements $\{p_{i0}\}$. This must be precisely equal to the number of new entrants; hence, one may substitute in eqn [11] to give

$$n(T+1) = n(T)P + n(T)p_0'r = n(T)\left[P + p_0'r\right]. \qquad [13]$$

It is easy to verify that the matrix in square brackets is a stochastic matrix (i.e., its rows all sum to 1). Hence, this model may be treated exactly as the closed model discussed above with the matrix $P + p_0'r$ replacing $\boldsymbol{P}$ of eqn [9].

Practical Issues with Markov Models

The Choice of Categories in a Markov Model

The most restrictive assumption of Markov models is that each transition probability depends only on the current state and not on any preceding states. In practice, this is often not realistic. For example, when studying a manpower system, the chance of an upward move (promotion) may depend on both the category (grade) and the length of time spent in that grade. If one ignores that dependence, predictions are likely to be in error. This problem can be circumvented by subdividing the grades and forming subgrades according to length of service. Thus, one would have a new grade consisting of those originally in grade 1 and having length of service up to 1 year; there would be a new second category consisting of those originally in grade 1 with between 1 and 2 years of service and so on. One could then model the new system more accurately because the effect of length of service would now have been taken account of in forming the grades. Before making the final predictions, the new categories can be recombined. In principle, the system could be made ever more Markovian by incorporating any other variables on which propensity to be promoted depended. However, there is a practical limit to the extent to which this device can be used. In practice, the transition probabilities will usually be unknown and so have to be estimated from flow data. The finer the subdivision, the less precise will the estimates of the transition probabilities become and, consequently, the errors of any predictions will be increased. A balance has to be struck between making the model more realistic and reducing the uncertainties of prediction.

Discrete Time and Continuous Time Systems

The choice between discrete and continuous time models is partly a matter of practical realism and partly of mathematical convenience. The development of the theory viewed in a historical perspective shows that realism and convenience have often combined to favor one or the other. In the case of Markov models, for example, changes of state often do, in fact, occur at fixed intervals of time, as when students in an educational system change state once every academic year. It is thus natural to formulate models of such systems in discrete time. Even in manpower systems, where change may take place at any time, it may be convenient to account for movements on a weekly or monthly basis. For such reasons, most of the relevant theory has been developed in discrete time. Nevertheless, it is worth observing that the theory described is closely paralleled by models in continuous time. Thus, in the case of the waiting time distribution discussed in the section A Simple Example (The Poisson Model), the time interval of the discrete model was allowed to become very small. The transition probabilities then became infinitesimal and the coefficients of δt became transition rates. Fuller details are given in, for example, Bartholomew (1982, Chapters 4 and 5).

When one moves on to other models, much of the theory required has been obtained, for various reasons, from first principles, in continuous time and this fact has largely determined the direction that research has taken. For example, this is true in the case of renewal models and most of the models for the diffusion of news and innovations. In the latter case, the pioneering work was in the field of epidemics where it is more natural and convenient to work in continuous time. As this is a review article, the author has followed established practice and the reader will note a shift from predominantly discrete time models to continuous models at this point.

Deterministic and Stochastic Models

The derivation of some of the models considered here, and certainly their use, has often proceeded as if all change was deterministic. A model devised on such principles may be described as a deterministic model. The distinction may be made clear by taking a particular case. In the Markov model, transition probabilities were introduced to describe the movement of individuals between states. Thus, p_{ij} was the probability of moving from i to j. The actual number moving would be a random variable with a binomial distribution and parameters n and p_{ij} and mean np_{ij}. If, by contrast, the number moving were supposed to be the exact number np_{ij}, one would have the deterministic equivalent of the Markov model. The expectations of the numbers in the stochastic version thus correspond with actual numbers in the deterministic version. If all one is interested in is the expectations, it might seem simpler to work deterministically from the start using averages instead of actual numbers. There is no distinction in the case of Markov models because the equations are linear. The stochastic model gives us much more, of course, enabling us, for example, to compute variances and covariances of the state numbers. But in

much practical work, in manpower planning, for example, predictions have not gone beyond the expectations and the deterministic interpretation suffices.

When one moves on to diffusion models, the linearity is lost and it is no longer true that the expectations derived from the stochastic model coincide with predictions of its deterministic counterpart. At best, the deterministic model serves as an approximation to the stochastic model when the numbers are large.

Renewal Models and Vacancy Chains

Basic Ideas

The author has considered a Markov model with a fixed total size. In some fields, the sizes of all categories are fixed. In such cases, the basic accounting relations expressed in eqn [7] still hold but the stock numbers on the left-hand side are now given numbers. This places severe constraints on the flows. Under these circumstances, one must begin by specifying what drives the system or, what initiates movement. Normally, such a system will be open with outgoing flows, which create the need to maintain the stock levels. This movement will then generate consequential flows within the system. Two approaches to modeling such systems have been explored. One draws on renewal theory whose origins are in population mathematics and the theory of industrial replacement. The author describes this below. The second was proposed by Harrison White (1970) in work on what he called 'chains of opportunity.' Modeling vacancy chains inverts the usual viewpoint by modeling the flows of vacancies rather than the flow of people. If a person leaves the system, the assumption that each category is of fixed size means that a vacancy is created. When that vacancy is filled from elsewhere in the system, one may think of the vacancy as moving to the place from where that replacement came. That movement will create a new vacancy (which can be thought of as moving elsewhere in the system) from where that replacement came. In general, every movement of a person is associated with a movement of a vacancy in the opposite direction. If one could assume that the movement of a vacancy was governed by a Markov chain, one could model the movements of vacancies in the system using Markov chain theory. This possibility has been explored for manpower systems in Bartholomew et al. (1991). More recently, the idea has been used in the study of housing markets (see Magnusson Turner, 2010), for example, where the creation of new housing stock creates vacancies into which people move from existing housing.

A Simple Renewal Model

Renewal models are another kind of stochastic model that has been used in the study of social processes and here the author describes a simple example. They have almost always been developed in continuous time, although a discrete time version of the most elementary example was actually included, as a special case, in the Markov model for a system of fixed size. Here, one deals with a similar case in continuous time because it has important, and perhaps surprising, practical implications.

Suppose that there is a system consisting of N persons and that that number remains fixed. The individuals who populate the system are assumed to behave independently and the uncertainty arises from not knowing when they will leave. This uncertainty is expressed by a hazard function defined as follows.

$$\Pr\{\text{loss occurs in } (t, t+\delta t)\} = \lambda(t)\delta t + o(\delta t). \qquad [14]$$

An increasing hazard function means that the individual is more likely to leave as time passes; a decreasing function means the opposite and more subtle changes can be expressed by more complicated functions.

The number of people who are expected to leave, which of course is exactly equal to the number joining, is given by the 'renewal function.' This function is denoted by $r(T)$ and is derived by a straightforward probability argument that shows that it satisfies the following integral equation

$$Nr(T) = Nf(T) + N\int_0^T r(T-t)f(t)\mathrm{d}t \qquad [15]$$

where $f(t)$ is the probability density function of lifetime in the system and $Nr(T)\delta t$ is the expected number of replacements required in the interval $(T, T+\delta T)$.

In principle at least, this equation can be solved mathematically by the use of Laplace transforms or numerically, using a discrete approximation. However, there is one case where the solution is immediate. This is when the life distribution is exponential – a distribution already met in eqn [6]. In that case, the hazard function is constant and so it turns out is the renewal function. Furthermore, the renewal function is also constant and equal to μ^{-1}, where μ is the average length of stay. This result accords with intuition because it says that if the average stay, for example, were 4 years, then the rate of leaving and replacement would be 25%. If this were a good approximation when the life distribution was not exponential, there would be little more to be said. But unfortunately, this is not the case for the life distributions that occur, for example, in labor wastage or house occupancy. In such cases, the hazard function is not constant but often declines quite steeply over most of its range. This means that the longer an individual has been in the system, the less likely they are to leave. If this happens, the short-term loss rate may be very far from the equilibrium value and then a solution to eqn [15] is necessary.

Nonlinear (Diffusion) Models

In this section, one turns to models that may be described as nonlinear. The Markov models discussed above were linear in the sense that the number moving between category i and category j depended only on the number in category i and this made the model linear. There are many social processes where transition depends on the numbers in more than one category in a nonlinear fashion. Although the fields of application are diverse, they share a common mathematical structure. The earliest application goes back to the 1950s when Anatol Rapport was studying what he called the random net, which had to do with the connectedness of neural arcs and the possibility of random connections

allowing transmission through the net. Next came the epidemic theory, where an infectious disease might spread through a population as a result of random contacts between members of the population. This was easily extended and modified to cover the spread of news or rumors through populations of randomly mixing populations. Less obvious, perhaps, is the example of social groups competing for membership and this is the example the author shall use here to illustrate the typical problems that arise. Cross-fertilization has been hampered by the varied disciplinary allegiances of researchers in the field and the journals that have published their work, for example, the spread of information as described in Rabajante (2012).

In the simplest case, there are two groups, political parties say, competing for members in a population of fixed size. At any time, the population may be divided into three groups: those who are members of group 1, those who are members of group 2, and those who are unaffiliated. The composition of the population changes as a result of the following events. A member of group 1 meets an uncommitted person and recruits them to membership of that group, a member of group 2 similarly recruits an uncommitted member, or members of one group meet members of the other group and convert them to membership of their own group. Members of either group may also withdraw from membership and so become unaffiliated. It is assumed that the population is homogeneously mixing, which means that any pair is just as likely to meet as any other pair. On meeting, either member of the pair may change state according to rules that must be specified. This may be formalized as follows.

The state of the whole system may be described by the number of members of the two groups. In any small interval of time of length δT, any one of the following transitions may take place:

(1) $(n_1, n_2) \rightarrow (n_1 + 1, n_2)$
(2) $(n_1, n_2) \rightarrow (n_1, n_2 + 1)$
(3) $(n_1, n_2) \rightarrow (n_1 - 1, n_2)$
(4) $(n_1, n_2) \rightarrow (n_1, n_2 - 1)$
(5) $(n_1, n_2) \rightarrow (n_1 - 1, n_2 + 1)$
(6) $(n_1, n_2) \rightarrow (n_1 + 1, n_2 - 1)$

The probabilities of these various transitions will depend on two things. First, on the parameters chosen to reflect the effectiveness of the effort made to affect recruitment, conversion, or in the case of (3) and (4), the propensity for membership to lapse. Second, on the chance that a contact of the designated kind will take place. Thus, for example, the infinitesimal probability of transition (1) may be written,

$$\beta_1 n_1(T)\{N - n_2(T) - n_2(T)\}\ \delta T \qquad [16]$$

where $\beta_1 \delta T$ is the infinitesimal probability that a member of group 1 will recruit an uncommitted person when contact is made. The number of such pairs is given by the remaining part of the expression in eqn [16]. It is clear from eqn [16] why the model is called nonlinear; this probability is a quadratic function of the numbers in the states.

It is not possible to obtain exact expressions for the probabilities of the system being found in any state (n_1, n_2) at time T, but various partial or approximate methods are available. One is to exploit the power of computers to simulate the process. This permits experimentation with different parameter values and the relaxation of the highly restrictive assumption of homogeneous mixing. The direction in which recent research on these lines is taking can be seen in Gong and Xiao (2007). A second approach is to ignore the time element of the model and study the sequence of states through which the system passes with a view to studying the terminal behavior. This is facilitated by the fact that the process defined can be shown to be an absorbing Markov chain defined on the set of states of the form (n_1, n_2). A third approach is to use what is called a deterministic approximation, which replaces the infinitesimal transition probabilities by proportions. In this case, the rates of change of the state numbers can be expressed as linear functions of the state numbers. By this method, one can also investigate possible equilibria that occur when the derivatives are zero.

Stochastic Optimization

Lauren A Hannah Columbia University, New York, NY, USA

Published by Elsevier Ltd.

Abstract

In statistical science, stochastic optimization refers to a collection of methods for minimizing or maximizing an objective function when randomness exists. Over the last few decades these methods have become important tools in both academia and industry. Specific applications include: running simulations to refine the placement of acoustic sensors on a beam, deciding when to release water from a reservoir for hydroelectric power generation, and optimizing the parameters of a statistical model for a given dataset. Randomness usually enters these problems in two ways: through the cost function or the constraint set. Although stochastic optimization refers to any optimization method that employs randomness, this article only addresses settings where the objective function or constraints are random.

Introduction

Stochastic optimization refers to a collection of methods for minimizing or maximizing an objective function when randomness is present. Over the last few decades these methods have become essential tools for science, engineering, business, computer science, and statistics. Specific applications are varied, but include: running simulations to refine the placement of acoustic sensors on a beam, deciding when to release water from a reservoir for hydroelectric power generation, and optimizing the parameters of a statistical model for a given data set. Randomness usually enters the problem in two ways: through the cost function or the constraint set. Although stochastic optimization refers to any optimization method that employs randomness within some communities, we only consider settings where the objective function or constraints are random.

Like deterministic optimization, there is no single-solution method that works well for all problems. Structural assumptions, such as limits on the size of the decision and outcome spaces, or convexity, are needed to make problems tractable. Because solution methods are tied to problem structure, we divide this article according to problem type and describe the associated solution methods.

The most prominent division is between solution methods for problems with a single-time period (single-stage problems) and those with multiple time periods (multistage problems). Single-stage problems try to find a single, optimal decision, such as the best set of parameters for a statistical model given data. Multistage problems try to find an optimal sequence of decisions, such as scheduling water releases from hydroelectric plants over a 2-year period. Single-stage problems are usually solved with modified deterministic optimization methods. However, the dependence of future decisions on random outcomes makes direct modification of deterministic methods difficult in multistage problems. Multistage methods are more reliant on statistical approximation and strong assumptions about problem structure, such as finite decision and outcome spaces, or a compact Markovian representation of the decision process. The second section describes solution methods for single-stage stochastic optimization problems and the third section gives methods for sequential problems. Conclusions and areas for advancement are given in the last section.

Single-Stage Stochastic Optimization

Single-stage stochastic optimization is the study of optimization problems with a random objective function or constraints where a decision is implemented with no subsequent recourse. One example would be parameter selection for a statistical model: observations are drawn from an unknown distribution, giving a random loss for each observation. We wish to select model parameters to minimize the expected loss using data.

To generalize the problem, we begin by introducing some formal concepts and notation. Let $\mathcal{X}$ be the domain of all feasible decisions and x a specific decision. We would like to search over $\mathcal{X}$ to find a decision that minimizes a cost function, F. Let ξ denote random information that is available only after the decision is made. Unless otherwise noted, we will limit our discussion to random cost functions, denoted $F(x, \xi)$ (random constraint sets can be written as random cost functions). As we cannot directly optimize $F(x, \xi)$, we instead minimize the expected value, $\mathbb{E}[F(x,\xi)]$. The general single-stage stochastic optimization problem becomes.

$$\zeta^* = \min_{x \in \mathcal{X}} \{f(x) = \mathbb{E}[F(x,\xi)]\} \qquad [1]$$

Define the set of optima as $\mathcal{S}^* = \{x \in \mathcal{X} : f(x) = \zeta^*\}$. For all single-stage problems, we assume that the decision space $\mathcal{X}$ is convex and the objective function $F(x, \xi)$ is convex in x for any realization ξ. Problems that do not meet these assumptions are usually solved through more specialized stochastic optimization methods like the stochastic ruler (Alrefaei and Andradottir, 2001), nested partitions (Shi and Olafsson, 2000), branch and bound (Norkin et al., 1998), or tabu search (Battiti and Tecchiolli, 1996; Glover and Laguna, 1999). In this section, we begin by outlining a set of problem considerations and then review four broad solution methods problem [1]: sample average approximation (SAA), stochastic approximation, response surfaces, and metamodels.

Problem Considerations

Stochastic optimization has been studied in a broad set of communities that each developed methods to solve problems that were important to their own discipline. As such, there is no consensus about how data are generated or processed.

Each community has a set of tacit assumptions, such as observational data with exogenous noise in statistical inference problems, or generative data with endogenous noise in engineering design problems. The types of assumptions are rarely stated, but we find it helpful to discuss them and how they interact with solution methods.

Noise Generation: Exogenous versus Endogenous

The random outcome ξ is exogenous if the decision x does not affect the distribution of ξ. Likewise, noise is endogenous if the choice of x may affect the distribution of ξ. An example of exogenous noise would be returns for a portfolio of stocks: portfolio choice will not affect stock market returns. Endogenous noise can arise in problems like acoustic sensor placement on a steel beam (Sadegh and Spall, 1998): placement affects the recorded distortions.

Data Generation: Constructive versus Black Box

An observation of $F(x, \xi)$ is constructive if, for a given ξ, $F(x, \xi)$ can be evaluated for any x. This is common when F is a parametric model, like a log likelihood of parameters x given data realization ξ. Conversely, $F(x, \xi)$ is generated by a black box if $F(x, \xi)$ can only be generated for a specific x. Constructive data generation is only possible if the noise is exogenous.

Data Treatment: Batch versus Online

Solution methods have batch data evaluation if all of the observations of $(x_i, F(x_i, \xi))_{i=1}^n$ are used at once to generate a decision. An example would be maximum likelihood estimation for a parametric statistical model. Solution methods have online data evaluation if the decision is updated in a sequential manner using one observation at a time.

Data Type: Observational versus Generative

Data are observational if $(x_i, F(x_i, \xi))_{i=1}^n$ are generated a priori and the decision maker cannot generate any more. An example would be using n observations to fit a parametric statistical model. Data are generative if the decision maker can obtain samples for a new decision value, $(x_i, F(x_i, \xi_i))$, as needed. This is common in experimental settings where new observations can be generated by changing experimental parameters and rerunning the experiment. A poorly studied but common middle ground is partially observational data, where a decision maker can obtain new samples by controlling a subset of the parameters. An example would be temperature data in a building that is controlled by a thermostat set point: the set point can be changed by the decision maker, but other variables that influence the optimal decision, like occupancy level, cannot be changed.

Sample Average Approximation

SAA (Healy and Schruben, 1991; Robinson, 1996; Shapiro and Wardi, 1996; Shapiro et al., 2002) is a two-part method that uses sampling and deterministic optimization to solve eqn [1]. The first step in SAA is sampling. While directly computing the expected cost function, $\mathbb{E}[F(x, \xi)]$, is not possible for most problems, it can be approximated through Monte Carlo sampling in some situations. Let $(\xi_i)_{i=1}^n$ be a set of independent, identically distributed realizations of ξ, and let $F(x, \xi_i)$ be the cost function realization for ξ_i. The expected cost function is approximated by the average of the realizations:

$$\mathbb{E}[F(x, \xi)] \approx \frac{1}{n} \sum_{i=1}^{n} F(x, \xi_i) \qquad [2]$$

The second step in SAA is search. The right hand side of eqn [2] is deterministic, so deterministic optimization methods can be used to solve the approximate problem:

$$\zeta_n^* = \min_{x \in \mathcal{X}} \left\{ f_n(x) \frac{1}{n} \sum_{i=1}^{n} F(x, \xi_i) \right\} \qquad [3]$$

The set of approximate optima is $\mathcal{S}_n^* = \{x \in \mathcal{X} : f_n(x) = \zeta_n^*\}$.

Deterministic search is the main benefit of SAA. Many commercial software packages, including Matlab and R, offer implementation of basic deterministic optimization methods, while more specialized packages like CPLEX and Gurobi provide a wider array of deterministic methods. To guarantee convergence of the search method to a global optimum, it is assumed that $\mathcal{X}$ is convex and that $F(x, \xi_i)$ is convex in x for every realization of ξ. These assumptions can be lifted in exchange for a guarantee of only local optimality.

One of the main limitations is that SAA is only available for problems with exogenous noise and constructive data generation. It cannot accommodate any problems with black box generation. The data are processed in a batch manner. These rather strong assumptions allow the use of either observational or generative data.

Because of its inherent simplicity, SAA has been independently proposed in a variety of fields under a variety of names. A form of SAA was derived in the early statistics community as maximum likelihood estimation (Fisher, 1922), although it was not generalized to other types of stochastic optimization problems. SAA-type methods were generalized in the operations research community under a variety of names: sample path optimization (Robinson, 1996; Shapiro and Wardi, 1996; Gürkan et al., 1999), stochastic countermethods (Rubinstein and Shapiro, 1993), retrospective optimization (Healy and Schruben, 1991), scenario optimization (Birge and Louveaux, 1997), and SAA (Shapiro et al., 2002; Kleywegt et al., 2002). Applications for SAA include: chance constrained optimization (Pagnoncelli et al., 2009), discrete stochastic optimization (Kleywegt et al., 2002), stochastic routing (Verweij et al., 2003), queuing models (Atlason et al., 2004), asset allocation (Blomvall and Shapiro, 2006), and solving (Partially Observable) Markov Decision Processes ((PO)MDPs) (Ng and Jordan, 2000; Perkins, 2002).

Theoretical Properties of SAA Estimates

Like all stochastic optimization methods, SAA relies upon a collection of random variables to produce a statistical estimate. Most theoretical results follow directly from the Law of Large Numbers and Central Limit Theorem due to the construction of SAA. Under mild regularity conditions, for any fixed x the limiting distribution of the SAA estimate is Gaussian with mean $f(x)$ and variance $\sigma^2(x) = \mathrm{Var}(F(x, \xi))/n < \infty$:

$$n^{\frac{1}{2}}\left[f_n(x) - f(x)\right] \xrightarrow{d} N\left(0, \sigma^2(x)\right)$$

The symbol $\xrightarrow{d}$ denotes 'convergence in distribution.' Under more stringent conditions, including Lipschitz continuity of $F(\cdot, \xi)$, convexity of $F(x, \xi)$ and $\mathcal{X}$, and $f(x)$ having a unique optimum $S^* = \{x^*\}$, a similar result holds for the optimal values:

$$n^{\frac{1}{2}}\left[\zeta_n^* - \zeta^*\right] \xrightarrow{d} N(0, \sigma^2(x^*)) \qquad [4]$$

The limiting Gaussian distribution in eqn [4] can be used to determine the number of samples needed to generate an $\varepsilon-$optimal solution with at least probability $1 - \alpha$. An $\varepsilon-$optimal solution is defined as any solution $\tilde{x} \in \mathcal{X}$ such that $f(\tilde{x}) \leq \zeta^* + \varepsilon$ for a specified $\varepsilon > 0$. However, there is a tradeoff between the accuracy of f_n and the time needed to search f_n. In the general case, with efficient search algorithms the additional computational complexity is roughly on the order of n (Shapiro, 2013). See Shapiro (1991), Rubinstein and Melamed (1998), and Shapiro et al. (2009) for a more complete discussion of SAA consistency and convergence rates.

Stochastic Approximation

Stochastic approximation is an iterative method that uses noisy observations to find the root of a function, g, i.e., the set of x where $g(x) = 0$ (Robbins and Monro, 1951). When that function is the gradient of the expected cost function, $g(x) = \nabla_x f(x)$, stochastic approximation finds local optima of f for an unconstrained decision set using noisy subgradient observations, $g(x_i, \xi_i)$. In a generalization of stochastic gradient descent, a decision x_i is updated recursively by moving a distance a_i in the direction opposite the gradient:

$$x_{i+1} = x_i - a_i g(x_i, \xi_i) \qquad [5]$$

A constraint set, $\mathcal{X}$, can be included through a projection operator $\Pi_{\mathcal{X}}$ that maps $x_i - a_i g(x_i, \xi_i)$ into the closest point of $\mathcal{X}$. The main considerations for eqn [5] are selecting a step size sequence $(a_i)_{i=1}^{\infty}$ and obtaining a gradient $g(x_i, \xi_i)$ through direct observation or estimation.

Stochastic approximation has a less restrictive set of assumptions than SAA: data generation may be either constructive or black box, and noise generation may be either endogenous or exogenous. If the data have exogenous noise and constructive generation, then observational data may be used. If those conditions are not met, generative data are required. Finally, stochastic approximation uses online data processing. This has made stochastic approximation one of the most prominent methods for large-scale statistical inference; see Bottou (2010), Hoffman et al. (2010), and Agarwal et al. (2012) for examples. For n observations, SAA requires n evaluations of the derivative of a log-likelihood function per iteration of the deterministic solver, which can become unreasonably expensive. In extremely large-scale inference, it may even be problematic to store n observations in RAM. Stochastic approximation requires only n evaluations of the derivative of the log-likelihood function and allows data streaming from an external storage device.

Gradient Approximation

Gradients can be computed through either direct observation or statistical estimation. Direct computations are usually possible when the loss function has a closed form, as in case of parametric statistical inference. In contrast, the gradient must be estimated when the data are generated by a black box. Finite difference (Kiefer and Wolfowitz, 1952) and related methods (Spall, 1992) approximate the gradient by using the current decision, x_t, as a starting point and adding a perturbation, $e_j c_i$. Here e_j denotes a vector of all 0's with a 1 in the jth location and $(c_i)_{i=1}^{\infty}$ is a sequence of perturbation sizes that decreases to 0. The jth entry of the gradient is approximated by:

$$[g(x_i, \xi_i)]_j = \frac{F(x_i + c_i e_j, \xi_{i,1}) - F(x_i - c_i e_j, \xi_{i,2})}{2c_i} \qquad [6]$$

Estimates from eqn [6] can be made more stable by using minibatches. Full finite difference computations may become infeasible when $F(x_i, \xi_i)$ is computationally expensive or p is large. Alternatives include one-sided differences, requiring $p + 1$ evaluations, and simultaneous perturbation analysis (Spall, 1992), which generates an estimate by adding and subtracting a random perturbation vector to get an estimate with two observations.

Step Size Selection

The step size sequences $(a_i)_{i=1}^{\infty}$ and $(c_i)_{i=1}^{\infty}$ affect whether the stochastic approximation estimator converges to a locally optimal solution and the rate at which it converges. In general, convergence for stochastic approximation with a directly computed gradient is guaranteed if

$$\sum_{i=1}^{\infty} a_i = \infty, \quad \sum_{i=1}^{\infty} a_i^2 < \infty, \quad a_i > 0 \qquad [7]$$

Generally, $(a_i)_{i=1}^{\infty}$ is chosen such that $a_i = Ci^{-\alpha}$ for $\alpha \in (½, 1)$ and a positive constant C. There is a tradeoff between the rate of convergence and robustness of the estimator: $\alpha = 1$ generally promises the best asymptotic rate in many circumstances, but is sensitive to misspecification of C or nonstrong convexity of f. If second order information is available, a_i can be replaced by an approximation of the inverse of the Hessian of f (Bottou, 2010).

When gradients are estimated, the perturbation sequence $(c_i)_{i=1}^{\infty}$ needs to be chosen in conjunction with $(a_i)_{i=1}^{\infty}$. Traditional constraints require that in addition to eqn [7], the sequences satisfy (Kiefer and Wolfowitz, 1952):

$$\sum_{i=1}^{\infty} \frac{a_i^2}{c_i^2} < \infty, \quad \sum_{i=1}^{\infty} a_i c_i < \infty, \quad c_i > 0$$

However, slightly looser constraints do exist (Broadie et al., 2011). Parameters are commonly set as polynomial sequences with $a_i = Ci^{-1}$ and $c_i = Di^{-1/4}$ for positive constants C and D.

Theoretical Properties of Stochastic Approximation

Convergence theory for stochastic approximation generalizes convergence theory for gradient descent algorithms. Rates depend on the shape of f and whether the gradients are exact or estimated. Common shape assumptions are smoothness – whether f is Lipschitz and has Lipschitz first order derivatives – and strong convexity:

$$(\nabla f(x) - \nabla f(y))^T (x - y) \geq m\|x - y\|_2^2$$

for all $x, y \in \mathcal{X}$, where $m > 0$ is a curvature constant. In all instances, we use n iterations and assume a few mild regularity conditions. If the gradients are not estimated, f is smooth and strongly convex, and $a_i = Ci^{-1}$, then the convergence rate is $\mathcal{O}(n^{-1})$:

$$\mathbb{E}[f(x_n) - f(x^*)] \leq Kn^{-1}$$

for a constant $K > 0$ if $mC > 2$. However, if $mC < 2$, then an arbitrarily poor rate $\mathcal{O}(n^{-mC/2})$ is obtained (Nemirovski et al., 2009; Bach and Moulines, 2011). If the gradient is estimated, rates of $\mathcal{O}(n^{-1/2})$ can be obtained using $a_i = Ci^{-1}$ and $c_i = Di^{-1/4}$ (Broadie et al., 2011). When f is nonstrongly convex or nonsmooth, the best general convergence rate is $\mathcal{O}(n^{-1/2})$ (Bach and Moulines, 2011).

Stochastic approximation can be made more robust to parameter misspecification through a combination of step sizes larger than $\mathcal{O}(n^{-1})$ and iterate averaging (Polyak and Juditsky, 1992; Ruppert, 1988; Nemirovski et al., 2009). The most common averaging scheme is Polayk-Ruppert averaging:

$$\bar{x}_n = \frac{1}{n}\sum_{i=1}^{n} x_i$$

where $x_1, \ldots, x_n$ are generated through the usual stochastic approximation recursion. For a strongly convex, smooth objective function, a step size $a_i = Ci^{-\alpha}$ with $\alpha \in [½, 1]$ will yield rates of $\mathcal{O}(n^{-1})$ using iterate averaging (Bach and Moulines, 2011). For convex, nonsmooth or nonstrongly convex objective functions, iterate averaging will give a rate of $\mathcal{O}(n^{-1/2})$ for $\alpha = 1/2$ (Nemirovski et al., 2009). In general, using $\alpha = 1/2$ and iterate averaging is a good choice because it is adaptive to strong convexity while being robust to nonsmoothness and nonstrong convexity.

Response Surfaces

Response surface methodology (RSM) is a collection of methods that fit a surface to a set of decision–response pairs and then search the surface to find a new decision. Traditionally, RSM refers to online methods for decision making: a collection of decision–response pairs are sampled around a current decision, a 'response surface' is fitted locally to the observations, and then decision is updated by searching the local surface. Some authors have placed batch methods under the umbrella of RSM (Downing et al., 1985; Lim, 2010), but we categorize these as global metamodels. RSM originated as methodology for optimizing conditions for chemical investigation in the 1950s (Box and Wilson, 1951), and has since been widely applied in experimental design, process optimization, and simulation optimization. Recent surveys and books include Barton and Meckesheimer (2006), del Castillo (2007), Myers et al. (2009), and Barton (2013).

RSM proceeds in a manner similar to stochastic approximation. A starting point, x_0, is selected. Then configurations around this point are sampled and used to fit a first or second order polynomial (Box and Draper, 1987). Expected values in a local area around the current decision x_i are estimated by:

$$\begin{aligned} \widehat{y}(x_i) &= \beta_0 + \beta_{1:p}^T x_i && \text{(linear)} \\ \widehat{y}(x_i) &= \beta_0 + \beta_{1:p}^T x_i + x_i^T \mathbf{B} x_i. && \text{(quadratic)} \end{aligned}$$

Typically, a linear model is used in earlier iterations while a quadratic model is used in later ones. Sampling design near x_i is often based on experimental design literature for parametric models (Montgomery, 2012) and model fit is evaluated with standard parametric statistical tools (Kleijnen and Sargent, 2000). The decision is updated by moving from the current decision in the direction of steepest descent. For a locally linear model, this is

$$x_{i+1} = x_i - a_i \beta_{1:p}$$

The step size a_i is often set as the quasi-Newton step size with the local surface as the objective function (Kleijnen, 2008) or through a line search (Barton and Meckesheimer, 2006). Once the estimated slopes get close to zero, a second order model is used to check optimality conditions through hypothesis testing.

Response surfaces have the same data generating requirements as stochastic approximation: data generation may be either constructive or black box, and noise generation may be either endogenous or exogenous. If the data have exogenous noise and constructive generation, then observational data may be used; otherwise, generative data are required.

Global Metamodel Optimization

Metamodels relate a set of inputs to an expected output through regression. Response surfaces are one form of metamodel, as are the Monte Carlo objective function approximations formed by SAA. In contrast to local response surfaces, global metamodels define a relationship that is valid across all feasible input values. A variety of regression methods have been used to fit global metamodels, including radial basis functions (Shin et al., 2002), neural networks (Anjum et al., 1997), Gaussian processes/stochastic kriging (Ankenman et al., 2010), and shape constrained nonparametric regression (Lim, 2010; Hannah et al., 2013). Metamodels have been used for optimization for both batch and online problems.

In the batch setting, global metamodel optimization is done through a two-step process much like SAA. Before any modeling is done, n decision–response pairs, $(x_i, y_i)_{i=1}^n$ where $y_i = F(x_i, \xi_i)$, are collected. Then a metamodel, $f_n : \mathcal{X} \to \mathbb{R}$, is fit to $(x_i, y_i)_{i=1}^n$ through regression. Finally, the decision is generated by solving

$$\zeta_n^* = \min_{x \in \mathcal{X}} f_n(x)$$

Batch global metamodel optimization is primarily useful for inferring a decision from observational data generated by a black box with either endogenous or exogenous noise. Note that most regression methods, like neural networks, basis function regression, and Gaussian processes, are not shape-constrained: f_n is not guaranteed to be convex and must either be optimized locally or through global optimization methods. Recently, there has been some work on using shape-constrained regression to maintain metamodel convexity (Lim, 2010; Hannah et al., 2013).

Global metamodel optimization has recently gained popularity for online optimization of functions that are costly to evaluate, such as hyperparameter tuning for Bayesian

models (Scott et al., 2011; Snoek et al., 2012). The metamodels used are generative models, like Gaussian processes, which give a distribution over possible expected value functions. Design locations are then selected recursively to minimize an error metric, such as the expected minimal value given the new design location. After each design location is selected, the metamodel is updated. Selected design locations generally try to balance gaining knowledge about a region with high uncertainty against tuning decisions in an area that is known to perform well. Online global metamodels require generative data.

Along with potential search difficulties, global metamodel optimization is limited by the amount of data for the regression step. Nonparametric metamodels require that n grows exponentially with the dimension of $\mathcal{X}$. This issue can be bypassed by using models with strong assumptions, like parametric relationships.

Multistage Stochastic Optimization

Multistage stochastic optimization problems aim to find a sequence of decisions, $(x_t)_{t=0}^{T}$, that minimize an expected cost function. The subscript t denotes the time at which decision x_t is made. Usually decisions and random outcomes at time t affect the value of future decisions. An example would be making a move in a chess game. With a move, the player may capture one of his or her opponent's pieces, change his or her board position, and alter his or her possible future moves. He or she needs to account for these issues to select the move that maximizes his or her probability of winning. Mathematically, we can describe multistage stochastic optimization problems as an iterated expectation:

$$\begin{aligned}\zeta^* = \min_{x_0\in\mathcal{X}_0} \mathbb{E}\Big[&\inf_{x_1\in\mathcal{X}_1(x_0,\xi_1)} F_1(x_1,\xi_1) \\ &+ \mathbb{E}\Big[\cdots + \mathbb{E}\Big[\inf_{x_T\in\mathcal{X}_T(x_{0:T-1},\xi_{1:T})} \gamma^{T-1}F_T(x_T,\xi_T)\Big]\Big]\Big]\end{aligned} \quad [8]$$

Here T is the number of time periods; $x_{0:t}$ is the collection of all decisions between 0 and t; ξ_t is a random outcome observable at time t; $\mathcal{X}_t(x_{0:t-1},\xi_{1:t})$ is a decision set that depends on all decisions and random outcomes between times 0 and t; $F_t(x_t, \xi_t)$ is a cost function for time period t that depends on the decision and random outcome for period t; and γ is the discount rate. The time horizon T may be either finite or infinite.

Unlike the methods outlined in Section Single Stage Stochastic Optimization, there are no multistage solution methods that work well for all problems within a broad class, like convex problems or Markov decision processes. The decision sequence space is affected by the curse of dimensionality: the size of the space grows exponentially with T, the number of possible outcomes for ξ_t, and the size of the decision space each time period, $\mathcal{X}_t$. Most successful methods are tailored to problem subclasses with exploitable structure, including bandit problems and Markov decision processes (MDPs). In this section, we break describe solution methods according to problem classes: bandit problems, MDPs, and convex multistage problems.

Bandit Problems

Bandit problems are sequential decision problems where each time period a decision maker has a choice of playing one of K slot machines, or 'one-armed bandits.' Each machine has a payoff that can take values zero or one according to a Bernoulli distribution with an unknown, arm-dependent probability of success p_k. The goal of the decision maker is to maximize his or her expected revenue or to minimize regret after T time periods. The decision $x_{t-1} \in \{1,\ldots, K\}$ is the selection of the arm to be played at time t, the random outcome ξ_t is a Bernoulli random variable with parameter $p_{x_{t-1}}$. The cost functions in eqn [8] for maximizing expected rewards and minimizing regret are as follows:

$$\begin{aligned} F_t(x_{t-1},\xi_t) &= -\xi_t && \text{(expected reward)} \\ F_t(x_{t-1},\xi_t) &= \mathbb{E}[\xi_t] - \max_{k=1,\ldots,K} p_k && \text{(regret)}\end{aligned}$$

Difficulty comes from the tradeoff between exploiting machines that have been observed to have high payouts and exploring new machines that have an uncertain payout probability. Solution methods can be divided by the size of K. When K is small each arm can be tried many times. When K is large the decision maker needs to borrow information from similar arms to estimate p_k, usually through regression. All bandit problems are online and assume generative data from a black box with endogenous noise.

Small K methods rely on computing a summary statistic for each arm, such as a mean value, upper confidence bounds (UCB) for p_k (Lai and Robbins, 1985; Audibert et al., 2009), knowledge gradient (Frazier et al., 2008), or Gittins index (Gittins, 1979). Once these have been computed, the arm with the highest value according to the statistic is played in the next round. These policies often result in asymptotic optimality.

When K is large, the arm space is often treated as a continuous space, $\mathcal{X}$. An arm mean function, $g(x)$, is assumed to have structure, often linearity, Lipschitz continuity, or a local Lipschitz continuity. The ellipsoid method creates an ellipse that has high probability of containing the optimal solution, which works well with linear mean functions (Dani et al., 2008). UCBs can be generated for problems with either Lipschitz or locally Lipschitz mean functions by using hierarchical models (Bubeck et al., 2011) or Gaussian processes (Srinivas et al., 2010).

Bandit problems can be extended to include 'side information,' which is an observable random variable that gives information about p_k. For instance, if p_k is an average click-through rate for an online advertisement, side information may be the advertiser, the user click history, zip code, etc. Bandit problems with side information are called 'contextual bandits.' Solution methods approximate the value of the arms as a function of the side information using regression methods like linear combinations of basis functions (Li et al., 2010), discretization of the state space (Rigollet and Zeevi, 2010; Perchet and Rigollet, 2013), random histograms (Yang and Zhu, 2002), nearest neighbors (Yang and Zhu, 2002) or adaptive partitioning (Slivkins, 2011). While all bandit problems are broadly applicable to many e-commerce problems like advertising and page layout, contextual bandits are particularly useful models for online advertising when there is information about the user and/or the advertisement.

Markov Decision Processes

MDPs simplify eqn [8] by assuming that the information required to make a decision at time t can be contained within a state, s_t. Naturally, this formulation includes all sequential decision processes the state is defined as the entirety of the decision and outcome history. However, MDPs are usually used to model problems where the state can take a small number of values that recur over time periods. For example, a state may be the position of a robot within a room where the goal is to navigate to a specific location while avoiding obstacles. Previous decisions, $x_{0:t}$, and random outcomes, $\xi_{1:t}$, are also summarized by the state. Due to the Markov nature of the problem, the cost function F_t is modified by removing the time index and including a dependence on the state to produce $F(x,s)$. The probability of transitioning from state s to state s' with decision x is $P_x(s,s')$. Traditionally, the time horizon is infinite. This allows optimality conditions to be expressed in terms of a value function $V(s)$, defined as the value of being in state s given that all subsequent decisions are optimal. The conditions are given by the Bellman optimality equation (Bellman, 1961):

$$\begin{aligned} V(s) &= \min_{x\in\mathcal{X}(s)} F(x,s) + \gamma \sum_{s'} P_x(s,s')V(s') \\ &= \min_{x\in\mathcal{X}(s)} F(x,s) + \gamma \mathbb{E}[V(s')|s,x] \end{aligned} \quad [9]$$

As eqn. [9] is recursive, it is convenient to use value functions that are generated by a policy π, which maps each state to a decision:

$$V^{\pi}(s) = F(x,s) + \gamma \mathbb{E}[V^{\pi}(s')|s,x] \quad [10]$$

where x is chosen according to a policy π.

Solution methods for MDPs usually involve two steps: estimating value functions for a given policy π, and using then the estimated value functions to find a better policy π',

$$\pi'(s) = \arg\min_{x\in\mathcal{X}(s)} F(x,s) + \gamma \mathbb{E}[V^{\pi}(s')|s,x] \quad [11]$$

Two of the most common solution methods are policy iteration and value iteration. Policy iteration selects a policy through eqn [11], and then updates value function estimates in eqn [10] using that policy. Value iteration combines the policy search and approximation steps by repeatedly solving:

$$\overline{V}_{i+1}(s) = \min_{x\in\mathcal{X}(s)} F(x,s) + \gamma \mathbb{E}[\overline{V}_i(s')|s,x] \quad [12]$$

where $\overline{V}_i$ is the estimated function after i iterations. See Sutton and Barto (1998) for a summary of these methods. Other solution techniques include rollout methods, which generate sample paths a few time periods into the future (Ng and Jordan, 2000), Q-learning, which fits a regression model to state–decision pairs (Watkins and Dayan, 1992), and dynamic programming, which is a computational method to solve finite horizon, discrete state, discrete decision problems (Sutton and Barto, 1998). MDPs usually assume generative, black box data with endogenous noise. Most solution methods are online, although some methods like fitted-Q iteration (Murphy, 2003; Antos et al., 2007) accommodate observational data in a batch setting.

MDP solution methods have many open research problems, including value function approximation, value attribution, and search over the decision space. Value function approximation is a form of regression, and it suffers the same problems as regression with regard to data sparsity in high dimensional state spaces. Proposed approximation methods have included lookup tables for small state spaces, linear combinations of a set of basis functions (Lagoudakis and Parr, 2003), nonparametric functions (Engel et al., 2003), or other problem specific representations that include hierarchical structure or convexity (Powell, 2011). Additionally, attributing value to actions when MDP has a single payout after a long string of decisions, such as winning a table tennis game, is notoriously difficult. Finally, all solution methods require a search over the decision space, as in eqns [11] and [12]. This is trivial when the decision space is finite and small, but can become difficult or impossible when the space is continuous and multidimensional.

Convex Multistage Problems

As in single-stage optimization, convexity of the cost function and decision space allows decision makers to leverage deterministic convex optimization methods. Convexity occurs in many operations research problems like resource allocation, inventory management, and portfolio management. We define convex multistage problems with respect to eqn [8]:

$F_t(x_t, \xi_t)$ is convex in x_t for each ξ_t and $\mathcal{X}_t(x_{0:t-1}, \xi_{1:t})$ is convex for all $x_{0:t-1}$ and $\xi_{1:t}$. In almost all situations the time horizon T is finite and relatively small. Solution methods include stochastic programming and approximate dynamic programming (ADP).

Stochastic programming solves eqn [8] by approximating it with a deterministic mathematical program, similar to SAA. One important but often unstated assumption is exogenous noise. It is described with a scenario tree. When n scenarios, $\omega_1, \ldots, \omega_n$, are expressed as a tree, each scenario is a path from the current state to a leaf of the tree, $\{\xi_1(\omega_i), \ldots, \xi_T(\omega_i)\}$. Scenario trees are often constructed through moment matching (Høyland and Wallace, 2001) or Monte Carlo methods (Blomvall and Shapiro, 2006), and each scenario can have nonuniform probability weights, $\{p_1(\omega_i), \ldots, p_T(\omega_i)\}_{i=1}^n$. Decisions are also indexed by scenario, $x = \{x_0(\omega_i), \ldots, x_T(\omega_i)\}_{i=1}^n$. The objective function is a linear combination of the costs for each of n scenarios:

$$f(x_{0:T}(\omega_1), \ldots, x_{0:T}(\omega_n)) = \sum_{i=1}^{n} \sum_{t=1}^{T} p_t(\omega_i) F_t(x_t(\omega_i), \xi_t(\omega_i)) \quad [13]$$

As with SAA, this is a batch method using observational data and constructive observed costs. The tree structure is maintained through nonanticipativity constraints: if ω_i and ω_j share a node at time t, then $x_t(\omega_i) = x_t(\omega_j)$. Each decision also needs to satisfy the original constraints for a given scenario, $x_t(\omega_i) \in \mathcal{X}_t(x_{0:t-1}(\omega_i), \xi_{1:t}(\omega_i))$. A solution is found by minimizing eqn [13] subject to the original and nonanticipativity constraints, often using dual decomposition methods (Ruszczyński, 1997).

Stochastic programming methods have been successfully implemented for short and medium term scheduling problems, including reservoir management (Tejada-Guibert et al., 1995), unit commitment for electricity generation (Takriti

et al., 2000), and asset management (Carino et al., 1994). Most computational difficulties come from large-scenario trees, which occur when there are long time horizons, finer time scales, or outcome spaces that are not well described by a sparse tree.

ADP uses ideas from MDPs to solve eqn [8], but it often has a finite time horizon and imposes shape constraints to allow search over continuous decision spaces. As in the MDP setting, the relevant historical decision and random outcome information is stored in a state variable, $(S_t)_{t=0}^{T}$, and the methods have the same data assumptions. ADP estimates a set of value functions to satisfy:

$$V_t(S_t) = \arg\min_{x_t \in \mathcal{X}_t(S_t)} \{F_t(x_t, \xi_t) + \gamma \mathbb{E}[V(S_{t+1})|S_t, x_t]\} \qquad [14]$$

As long as a convex approximation of $V_t(S_t)$ with respect to x_{t-1} is maintained, the convexity assumption allows efficient search over the decision space (Powell, 2011). The value functions are often fit through methods similar to value iteration or policy iteration. While ADP can scale to much larger problems than stochastic programming (Anderson et al., 2011), approximating value functions is a nontrivial statistical challenge: state variables can be high dimensional, simulation outputs can be limited, and shape constrained inference is difficult in multiple dimensions (Hannah and Dunson, 2013). Approximation methods have included basis functions linear projections (Tsitsiklis and Van Roy, 2001; de Farias and Van Roy, 2003; Keller et al., 2006), Benders cuts (Higle and Sen, 1991; Zakeri et al., 2000), and nonparametric regression (George et al., 2008; Deisenroth et al., 2009; Taylor and Parr, 2009). Consistency of ADP has not been shown in a general setting, although it has been demonstrated for certain cases (Nascimento and Powell, 2009).

Future Challenges and Closing Remarks

Due to the swift progress of data storage and analysis capabilities, stochastic optimization has been an area of extremely active research. Summaries of progress within specific fields are given by Fu (2013), Hutchison and Spall (2013), and Powell (2014). However, many important areas lacking solutions include the following.

Efficient Methods for Black Box, Observational Data

Observational data are currently handled through a global regression over the decision space, and problems with partially observational data receive little study. Methods that exploit convexity could drastically reduce data requirements and provide more reliable search.

Efficient Methods for Large Multistage Problems

While much attention has been given to value function approximation, discovering new problem subclasses with exploitable structure may prove more useful. Possible areas include the interplay between large decisions, such as 3-year operating goals for a hydroelectric plant, and small decisions, such as hourly water releases.

Solution Evaluation Methods

Asymptotic theory provides estimates on the quality of single-stage solutions, but in the multistage case asymptotic bounds either do not exist or they only provide pessimistic bounds. Some work in the operations research literature uses information relaxations to provide dual bounds (Haugh and Kogan, 2004; Brown et al., 2010), but these are computationally infeasible for general problems. Fast, reliable bounds would be useful for practitioners to assess decision quality before implementation.

Optimization in the presence of randomness is a fundamental problem in many fields. We fully expect that current methods for stochastic optimization will be refined over the next few decades while computational advances and new problems will lead to new opportunities for stochastic optimization research.

Stock Market Predictability

Burton G Malkiel, Princeton University, Princeton, NJ, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This survey reviews the findings of the empirical work concerning stock market predictability. It reviews the studies suggesting that future returns can be predicted on the basis of such fundamental variables as dividend yields, price earnings, price-to-book-value ratios, measures of systematic risk, and market capitalization (size). It also examines evidence that future prices exhibit short-term momentum and longer run mean reversion. The survey concludes by arguing that whatever predictable patterns do exist are unlikely to provide investors with a method to obtain extraordinary returns.

One of the most enduring cornerstones of modern financial theory has been that stock markets are reasonably efficient in reflecting new information and that price movements closely fit a random walk model where future prices cannot be predicted from an examination of past prices. Toward the end of the twentieth century, however, financial economists and statisticians began to question received doctrine, and many came to believe that stock prices were at least partially predictable. For example, stocks that perform the best over the preceding 3–12 months continue to outperform over the subsequent 5–12 months. Moreover, although far more controversial, many have argued that these predictable patterns enable investors to earn excess risk-adjusted rates of returns and provide evidence that the efficient market theory should be rejected. This survey reviews the findings of the empirical work concerning stock market predictability. It reviews the work done on stock prices that appears to reject the random walk hypothesis and looks at the body of studies suggesting that future returns can be predicted on the basis of such fundamental variables as dividend yields, price earnings (P/E), price-to-book-value (P/BV) ratios, measures of systematic risk, and market capitalization (size). The survey also examines the relationship between predictability and market efficiency.

The Efficient Market Theory and Its Critics

The basic idea behind the efficient market theory is that securities markets are extremely efficient in digesting information about individual stocks or about the stock market in general. When information arises about a stock (or the market as a whole), the news spreads very quickly and is immediately incorporated into the prices of securities. Thus, neither technical analysis (an analysis of past price patterns to determine the future) nor fundamental analysis (an analysis of a company's earnings, dividends, future prospects, etc., to determine a stock's proper value) will help investors to achieve returns greater than would be obtained by buying and holding one of the broad stock market indices. The efficient market theory is associated with the idea of a 'random walk,' which is a term loosely used in the finance literature to characterize a price series where all subsequent price changes represent random departures from previous prices. The logic of the random walk idea is that if the flow of information is unimpeded and information is immediately reflected in stock prices, then tomorrow's price change will reflect only tomorrow's news and will be independent of the price changes today. But news is by definition unpredictable and, thus, resulting price changes must be unpredictable and random. As a result, prices fully reflect all known information, and even uninformed investors buying a diversified portfolio at the tableau of prices given by the market will obtain a rate of return as good as that achieved by market professionals. Discussions of the random walk hypothesis can be found in Samuelson (1965) and Fama (1970).

Academic work published mainly after the 1980s has tended to cast doubts on many of the tenets of the efficient market theory. This work has suggested that the random walk model is not supported and that future stock prices and returns can be predicted, at least in part, by an examination of past stock prices and certain 'fundamental' valuation methods such as the ratio of stock prices to earnings and book values. Moreover, some of this work has been interpreted as implying that markets are inefficient in the sense that arbitrage opportunities exist that enable investors to earn excess risk-adjusted returns.

The Major Predictable Patterns That Have Been Discovered

This article will now focus on the findings of empirical work about stock market predictability done from 1980 to 2011. The general thrust of much of the published academic work has been along the following two lines. First, it appears that there are many predictable patterns in the stock market. The stock market is *not* random. Indeed, a book published by Lo and MacKinlay (1999) has the arresting title, *A Non-Random Walk Down Wall Street*. Second, although this is far more controversial, many have argued that these predictable patterns enable an investor to earn big risk-adjusted rates of return and are proof that the efficient market theory is wrong.

There Is Some Evidence of Short-Run Momentum in the Market

When stock returns for individual stocks and market averages are calculated over various periods during the preceding year, there is positive serial correlation. For example, Jegadeesh and Titman (1993, 2001) find that momentum strategies based on 3-, 6-, and 12-month returns have been persistently profitable

 http://dx.doi.org/10.1016/B978-0-08-097086-8.71024-5

during the 1980s and the 1990s. A positive rate of return in one period is more likely than not to be followed by a positive return in the next period. The market is not a perfect random walk. Further evidence provided by Lo and MacKinlay uses a simple specification test based on variance estimators. Their test exploits the fact that the variance of the increments of a random walk is linear in the sampling interval. For example, if stock prices are generated by a random walk, then the variance of monthly sampled log-price relatives must be four times as large as the variance of a weekly sample. Using data over a 23-year time frame from 1962 to 1985, Lo and MacKinlay reject the random walk hypothesis. The rejection cannot be explained completely by infrequent trading (where news affects smaller company stocks with a lag because they trade less frequently) or by time-varying volatilities.

This work suggests that quantitative managers who use momentum to help guide purchases have some empirical support on their side. Whether this is a true inefficiency or not, however, is open to more question. Certainly, any investor who pays transactions costs is not able to outperform a buy-and-hold strategy because the kind of momentum that has been found is small relative to the transaction costs involved. In empirical tests, momentum strategies appear to work better with small stocks (where the strategy is harder to implement because of high transactions costs) than with larger stocks.

The source of momentum profits and the interpretation of the evidence are controversial. For example, Hong and Stein (1999) present a behavioral model based on the hypotheses that delayed overreaction to information pushes the price of winners (losers) above (below) their fundamental value. In subsequent periods, the stocks display momentum as they revert to their fundamental values. Others, such as Conrad and Kaul (1998), suggest that returns from momentum strategies are simply compensation for risk. Carhart (1997), in his study of mutual fund returns, uses momentum as a risk variable (along with capital asset pricing model (CAPM) beta, value, and size) to risk adjust returns. Positive momentum is considered to be strong relative performance over the preceding 12 months (not including the most recent month to allow for any short-term return reversals).

One aspect of the empirical work on momentum has been referred to as 'postearnings announcement drift.' The pattern goes back to Ball and Brown (1968), Rendelman et al. (1982), and Bernard and Thomas (1989). Stocks whose earnings exceed forecasts (whether from analysts or some autoregressive earnings model) do react positively, but the reaction is not immediate. The price keeps rising over subsequent days, weeks, and even months. This underreaction of market prices to earnings surprises appears to be one of the more robust short-horizon predictable patterns and has been explained in terms of 'limits to arbitrage' and market frictions. However, the effect is particularly strong for smaller, less liquid stocks, where transaction costs and market impact costs are likely to eliminate apparent arbitrage profits, as suggested by Chung and Hrazdil (2011).

Since 2010, there have been a number of exchange traded funds (ETFs) formed on the basis of momentum. Depending upon the benchmarks used, some of these momentum strategies executed with real money have outperformed standard buy-and-hold index funds, but most others have underperformed. (See, for example, the international momentum fund, ticker AIMOX, and compare its performance with the standard international index fund for institutional investors, ticker VINX, during 2011 and 2012. Also compare ASMOX (a small-cap momentum fund) with IWM (a Russell 2000 index fund).) These funds have also failed to perform consistently over time. It is therefore far from clear how dependable any momentum pattern that can be discovered will be. The market is not statistically a random walk, but it is nearly so.

But There Is Mean Reversion

Returns may be positively correlated for short periods, such as months or quarters, but when returns are measured over longer periods, such as 3 or 4 years, there tends to be negative correlation. Just as in the Bible 7 lean years followed 7 fat years, so in the stock market extraordinary returns are somewhat more likely to be followed by lackluster returns. For example, Fama and French (1988) demonstrated that long holding period returns are negatively serially correlated. The serial correlation is significant and implies that 25–40% of the variation in long holding period returns can be predicted on the basis of past returns. Similar results were found by Poterba and Summers (1988), who conclude that there is substantial mean reversion in stock market returns at longer horizons. Some studies have attributed this forecastability to the tendency of stock market prices to 'overreact.' DeBondt and Thaler (1985), for example, argue that investors are subject to waves of optimism and pessimism that cause prices to deviate systematically from their fundamental values and later to exhibit patterns of reversal. These findings give some support to investment techniques that rest on a 'contrarian' strategy, that is, buying the stocks, or groups of stocks, that have been out of favor for long periods of time, and avoiding those stocks that have had large run-ups over the last several years.

While there is considerable support for this view, it should be pointed out that such mean reversion is quite a bit weaker in some decades than it is in other periods. Indeed, the strongest empirical results come from periods including the Great Depression. The effect was relatively weak during the 1990s and the first decade of the 2000s. Moreover, such return reversals for the market as a whole may be quite consistent with the efficient functioning of the market and could result, in part, from the volatility of interest rates. There is a tendency when interest rates go up for stocks to go down, and as interest rates go down for stocks to go up. If, in fact, interest rates fluctuate over time, one will tend to get return reversals, or mean reversion, and this is quite consistent with the efficient functioning of markets where stock returns will need to go up or down to be competitive with bonds.

Moreover, it may not be possible to profit from the tendency for individual stocks to exhibit patterns of return reversals. For example, Fluck et al. (1997) simulated a strategy of buying stocks that had particularly poor returns over the preceding 3–5 years. They found very strong statistical evidence of return reversals, but it was truly reversion to the mean, *not* an opportunity to make extraordinary returns. They found that stocks with very low returns over the preceding 3–5 years had higher returns in the next period, but the returns in the next period were similar for both groups. While they found strong evidence of mean reversion, they could not confirm that

a contrarian approach would yield higher than average returns. There was a statistically strong pattern of return reversal, but not one that implied an inefficiency in the market that would enable investors to make excess returns.

There Do Seem To Be Some Seasonal Patterns in the Stock Market

A number of researchers have found that January has been a very unusual month for stock market returns. Returns from an equally weighted stock index have tended to be unusually high during the first 2 weeks of the year. The return premium has been particularly evident for small stocks, i.e., those with relatively small total capitalizations, as has been demonstrated by Keim (1983). Haugen and Lakonishok (1988) detail the high January returns in a book entitled *The Incredible January Effect*.

There also appear to be a number of seasonal effects. For example, French (1980) documents significant Monday returns. There appear to be significant differences in average daily returns in countries other than the United States, as summarized by Hawawini and Keim (1995). There also appear to be some patterns in returns around the turn of the month, as shown by Lakonishok and Smidt (1988), as well as around holidays, as shown by Ariel (1990).

The general problem with these anomalies, however, is that they are *not* dependable from period to period. The January effect has not been useful to investors through much of the 1990s and the early 2000s. Moreover, these nonrandom effects (even if they were dependable) are small relative to the transaction costs involved in trying to exploit them. They do not appear to offer investors any arbitrage opportunities that would enable them to make excess returns.

The Size Effect

Probably one of the stronger effects that investigators have found is the so-called size effect: the tendency over long periods of time for small stocks to generate larger returns than those of large stocks. Since 1926, small-company stocks in the United States have produced a rate of return about 1.5 percentage points larger than the returns from large-company stocks.

Fama and French (1992) looked at data from 1963 to 1990 and divided all stocks into deciles according to their size as measured by total capitalization. Decile 1 contained the smallest 10% of all stocks, while decile 10 contained the largest stocks. The results plotted in **Figure 1** show a clear tendency for the deciles made up of portfolios of smaller stocks to generate higher average monthly returns than deciles made up of larger stocks.

If the 'beta' measure of systemic risk from the CAPM is accepted as the correct risk measurement statistic, the size effect can be interpreted as indicating market inefficiency. This is so because portfolios consisting of smaller stocks have excess risk-adjusted returns. But any conclusion that an inefficiency exists involves accepting the joint hypothesis that a size effect is present *and* that the CAPM is correct. Fama and French point out, however, that the average relationship between 'beta' and return is flat – not upward sloping as the CAPM predicts. Moreover, within beta deciles, 10 portfolios constructed by size display the same kind of positive relationship shown in **Figure 1**. On the other hand, within size deciles, the

Figure 1 Average monthly returns for portfolios, formed on the basis of size; 1963–90. Source: Fama, E.F., French, K.R., 1997. The cross-section of expected stock returns. Journal of Finance 47(2), 427–465.

relationship between beta and return continues to be flat. Fama and French conclude that size may well be a far better proxy for risk than beta, and therefore that their findings should not be interpreted as indicating that markets are inefficient.

The dependability of the size effect is open to question. The size effect has not been consistent from one decade to the next. During the first decade of the twenty-first century, there was a pronounced size effect in United States and other world stock markets, where small-cap stocks produced substantially higher returns than large-cap stocks. But during the 1990s the opposite was true. Higher returns were earned on large-cap stocks. Moreover, some portion of the size effect may result from survivorship bias in currently available computer sources of past returns. Today's lists of companies include only small firms that have survived, not the ones that later went bankrupt. Thus, a researcher who examined the 10-year performance of today's small companies would be measuring the performance of those companies that survived – not of the ones that failed.

There Is Evidence That Stocks with Low P/E Multiples Generate Higher Returns Than Those with High P/E Multiples

As **Figure 2** shows, evidence first published by Nicholson (1960) and later confirmed by Ball (1978) and Basu (1983) indicates that low-P/E stocks provide higher rates of return than high-P/E stocks. This finding is consistent with the views of behavioralists (see, for example, Kahneman and Riepe,

Figure 2 Average monthly returns for portfolios, formed on the basis of price earnings (P/E) ratio; 1962–90. Source: Hawawini, G., Keim, D.B., 1995. On the predictability of common stock returns: worldwide evidence. In: Jarrow, R., Maksimovic, V., Ziemba, W. (Eds.), Handbooks in Operations Research & MS, vol. 9. Elsevier Science, Amsterdam, New York, pp. 497–544.

1998) that investors tend to be overconfident of their ability to project high earnings growth and thus overpay for 'growth' stocks. The finding is also consistent with the views of Benjamin Graham and David Dodd (1934), first expounded in their classic book on security analysis and later championed by the legendary US investor, Warren Buffett. Similar results have been shown for price/cash-flow multiples, where cash flow is defined as earnings plus depreciation and amortization, (see Hawawini and Keim, 1995).

Stocks with Low P/BV Ratios Generate Larger Returns than Stocks with High P/BV Ratios

The ratio of stock P/BV (the value of a firm's assets minus its liabilities divided by the number of shares outstanding) has also been found to be a useful predictor of future security returns. Low P/BV (along with low P/E) is considered to be another hallmark of the so-called 'value' in equity securities, and is also consistent with the view of behavioralists that investors tend to overpay for 'growth' stocks that subsequently fail to live up to expectations. Fama and French (1992) concluded that size and P/BV together provide considerable explanatory power for future returns and once they are accounted for, little additional influence can be attributed to P/E multiples. Fama and French (1997) also conclude that the P/BV effect is important in many world stock markets other than that of the United States.

Lakonishok et al. (1994) argue that such results raise questions about the efficiency of the market. But these findings do not necessarily imply inefficiency. P/BV may be a more accurate proxy for the systematic risk priced in the stock market than traditional estimates of the CAPM beta because of measurement errors in the traditional estimates. Indeed, this is the explanation Fama and French give for this predictable pattern.

While there has been a pronounced value effect over the entire period from the early 1960s to the 2011s, the effect is not dependable in all periods. The so-called 'value' stocks substantially underperformed 'growth' stocks (those with high P/E and high P/BV ratios) during the 1990s. Value stocks then produced outstanding relative returns from early 2000 to the end of 2006. For the next 5 years, through 2011, however, growth stocks enjoyed higher returns. In general, value stocks produce the best relative returns when valuation metrics are widely dispersed, as they were in January 2000 near the top of the 'dot-com bubble.' Finally, it should be noted that considerable merger and restructuring activity has made book value increasingly hard to interpret. Thus, it is far from clear that the pattern will continue.

The High Risk—Low Return Findings

As indicated above, the relationship between the beta and subsequent return is not upward sloping as the CAPM predicts. But then CAPM may turn out to be a particularly useful model that could generate exceptional returns. Papers by Frazzini and Pedersen (2011) and Baker et al. (2011) have simulated a strategy of initiating long positions in low-beta stocks and short positions in high-beta stocks to produce a beta-neutral portfolio. The simulated strategy has produced extraordinary results over a more than 40-year period from January 1968 to December 2008. A dollar invested in the lowest quintile beta portfolio grew to $60.46 ($10.25 in real terms). A dollar invested in the highest quintile beta portfolio grew to only $3.77 and fell to 69 cents in real terms. The same kind of result is obtained when using price volatility and idiosyncratic risk (see Ang et al., 2006) as well as in international markets. Whether such a pattern continues to hold if constrained investors no longer bid up the prices of high-beta stocks is open to question, as is the feasibility of the strategy in the presence of transactions costs and short-sale constraints. It should be noted, however, that both high-beta and low-beta ETFs began to be marketed in mid-2011. For at least the next year, the high-beta ETF underperformed its benchmark, while the low-beta fund exceeded its benchmark performance (see, for example, the performance of the Power Shares S&P 500 high-beta portfolio (SPHB) during 2011 and 2012).

Predicting Market Returns from Initial Dividend Yields

Another apparently predictable relationship concerns the returns realized from stocks and the initial dividend yields at which they were purchased. The data since 1926 for the United States are presented in Figure 3. The figure was produced by measuring the dividend yield of the broad stock market (in this case, the Standard and Poor's 500 Stock Index) each quarter between 1926 and 2001, and then calculating the market's subsequent 10-year total return through 2011. The observations were then divided into deciles depending upon the level of the initial dividend yield. In general, the figure shows that investors have earned a higher rate of return from the stock market when they purchased stocks with an initial dividend yield that was relatively high (the first three deciles), and a below-average rate of return when they purchased them at initial dividend yields that were low (the last three deciles).

Formal statistical tests of the ability of dividend yields (dividend-price ratios) to forecast future returns have been conducted by Fama and French (1988) and Campbell and Shiller (1988). Depending on the forecast horizon involved, as much as 40% of the variance of future returns can be predicted on the basis of initial dividend yields.

These findings are not necessarily inconsistent with efficiency. Dividend yields of stocks tend to be high when interest rates are high, and they tend to be low when interest rates are low. Consequently, the ability of initial yields to predict returns may simply reflect the adjustment of the stock market to general economic conditions. Moreover, the dividend behavior of US corporations may have changed over time (see Fama and French 1999). Companies in the twenty-first century may be more likely to institute a share repurchase program rather than increase their dividends. Thus, dividend yield may not be as meaningful as in the past. Moreover, it is worth pointing out that dividend yields were unusually low at the start of 1995. An investor who avoided US stocks then would have missed out on one of the steepest 5-year increases in stock prices in history.

Finally, this phenomenon does not work consistently with individual stocks. Investors who simply purchase a portfolio of individual stocks with the highest dividend yields in the market will not earn a particularly high rate of return.

One popular implementation of such a 'high-dividend' strategy is the 'Dogs of the Dow Strategy,' which involves buying the 10 stocks in the Dow Jones Industrial Average with the highest dividend yields. For some periods, this strategy handily outpaced the overall average, and so several 'Dogs of the Dow' funds were brought to market during the mid-1990s and aggressively sold to individual investors. Such funds generally underperformed the market averages during the next 5-year period.

Predicting Market Returns from Initial P/E Multiples

The same kind of predictability for the market as a whole has been shown for P/E ratios. The data are shown in Figure 4. The figure presents a decile analysis similar to that described for dividend yields above. Investors have tended to earn larger long-horizon returns when purchasing stocks at relatively low P/E multiples. Campbell and Shiller (1988) report R^2s of over 40% and conclude that equity returns have been predictable in the past to a considerable extent. Whether such historical relations are necessarily applicable to the future is another matter. Such an analysis conducted by Campbell and Shiller in December 1996 predicted a long-horizon (nominal) return for the US stock market close to zero.

Figure 3 The future 10-year rates of return when stocks are purchased at alternative initial dividend yields (divident/price (D/P)). Source: The Leuthold Group.

Figure 4 The future 10-year rates of return when stocks are purchased at alternative initial P/E multiples. Source: The Leuthold Group.

The findings presented to the Board of Governors of the Federal Reserve System led Alan Greenspan to question whether stock prices were exhibiting irrational exuberance, but the stock market continued to rally strongly through the first quarter of 2000.

The Adaptive Market Hypothesis

Financial economists have increasingly entertained the notion of temporary instabilities in the relationship between underlying economic relationships, as suggested by Stock and Watson (2003). This may be equally true of the question of stock market predictability. One useful development that has been championed by Lo (2004, 2008) is the 'adaptive market hypothesis' (AMH), where time-varying predictability may exist (see also Farmer and Lo, 1999; Farmer, 2002). For Lo's evolutionary AMH, the lack of stock market predictability is not an all-or-nothing condition, but rather one that can vary over time, depending on the characteristics of existing limits to arbitrage, market imperfections, and psychological biases. These factors can give rise to periods when stock returns are predictable and departures from the efficient market hypothesis (EMH) appear to exist. In this sense, EMH and behavioral finance can comfortably coexist. But investors do learn from past history, and it is not reasonable to expect that any predictable patterns will persist, except those that are based on differences in risk. While it is possible that $100 bills may be found on the ground from time to time, they should be picked up right away. They are unlikely to be sitting there for long and, as Grossman and Stiglitz (1980) have emphasized, they will be picked up only if their value exceeds the cost. To be sure, there appear to be many examples where asset prices reached such 'bubble' levels that, at least in retrospect, it seems obvious that corrections were inevitable and that markets were inefficient. The housing bubble that peaked in 2002 is one example, as is the Internet stock market bubble that peaked in 2000. And no one can reasonably argue that the prevailing prices in these examples were 'correct.' But the EMH does not require that prices be correct. Indeed, prices are always wrong. What EMH posits is that no one knows for sure whether the prices are too high or too low and that no obvious arbitrage possibilities exist to earn abnormal returns.

As discussed above, many analysts claimed during the 1990s that the stock market had reached bubble levels at prices substantially lower than were actually realized and many years before the actual peak. Similarly, the collapse of the housing bubble that led to the most severe world economic downturn since the Great Depression was not predicted by the monetary authorities. In the author's view, the correct conclusion is that we should be modest in our appraisal of how predictable asset prices really are. EMH remains an extremely useful hypothesis that is strongly supported by experience.

Concluding Comments

In summary, there are many statistically significant predictable patterns in the stock market. It is important to emphasize, however, that these patterns are not dependable in each and every period, and that some of the patterns based on fundamental valuation measures of individual stocks may simply reflect a better proxy for measuring risk. Moreover, many of these patterns could self-destruct in the future, as many of them have already done. Indeed, this is the logical reason why one should be cautious not to overemphasize these anomalies and predictable patterns.

Suppose, for example, that one of the anomalies is really true. Suppose that there is a truly dependable January effect, and that the stock market – especially stocks of small companies – will generate extraordinary returns during the first 5 days of January. What will investors do? They will buy late in December, on the last day of December, and sell on January 5. But then investors find that the market rallied on the last day of December and so they will begin to buy on the next-to-last day. Moreover, because there is so much 'profit taking' on January 5, investors will have to sell on January 4 to take advantage of this effect. Thus, to beat the gun, investors will have to be buying earlier and earlier in December, and selling earlier and earlier in January so that eventually the pattern will self-destruct. Any truly repetitive pattern that can be discovered in the stock market and can be arbitraged away will self-destruct. Indeed, the January effect became undependable after it received considerable publicity.

Similarly, suppose there is a general tendency for stock prices to underreact to certain news events, leading to abnormal returns to investors who exploit the lack of full immediate adjustment. 'Quantitative' investment managers will then develop strategies in an attempt to exploit the pattern. Indeed, the more potentially profitable a discoverable pattern is, the less likely it is to survive.

Moreover, many of the predictable patterns that have been discovered may simply be the result of data mining. The ease of experimenting with financial data banks of almost every conceivable dimension makes it quite likely that investigators will find some seemingly significant but wholly spurious correlation between financial variables or among financial and nonfinancial data sets. An amusing one that has been uncannily accurate in the past for US markets is the Super Bowl Indicator, which predicts the sign of market returns for the year by the winner of January's football Super Bowl. Given enough time and massaging of data series, it is possible to tease almost any pattern out of every data set. Moreover, the published literature is likely to be biased in favor of reporting such results. Significant effects are likely to be published in professional journals, while negative results, or boring confirmations of previous findings, are relegated to the file drawer or discarded. Data-mining problems are unique to nonexperimental sciences, such as economics, which rely on statistical analysis for their insights and cannot test hypotheses by running repeated controlled experiments.

An exchange at an academic symposium (Roll-Shiller, 1992) between Robert Shiller (1981), an economist who is sympathetic to the argument that stock prices are partially predictable and skeptical about market efficiency, and Richard Roll, an academic financial economist who was also a businessman managing billions of dollars of investment funds, is quite revealing. After Shiller stressed the importance

of inefficiencies in the pricing of stocks, Roll responded as follows:

> I have personally tried to invest money, my client's money and my own, in every single anomaly and predictive device that academics have dreamed up … I have attempted to exploit the so-called year-end anomalies and a whole variety of strategies supposedly documented by academic research. And I have yet to make a nickel on any of these supposed market inefficiencies…a true market inefficiency ought to be an exploitable opportunity. If there's nothing investors can exploit in a systematic way, time in and time out, then it's very hard to say that information is not being properly incorporated into stock prices (Roll and Shiller, 1992).

Finally, there is a remarkably large body of evidence suggesting that professional investment managers are not able to outperform index funds that simply buy and hold the broad stock market portfolio (see, for example, Malkiel, 2012). Three-quarters of professionally managed funds are regularly outperformed by a broad index fund with equivalent risk, and those that do appear to produce excess returns in one period are not likely to do so in the next. The record of professionals does not suggest that sufficient predictability exists in the stock market to produce exploitable arbitrage opportunities.

Pricing irregularities and predictable patterns in stock returns do appear over time and even persist for periods. Undoubtedly, with the passage of time and with the increasing sophistication of databases and empirical techniques, further apparent departures from efficiency, and further patterns in the development of stock returns, will be documented. But the end result will not be an abandonment of the belief of many in the profession that the stock market is remarkably efficient in its utilization of information and that whatever patterns do exist are unlikely to provide investors with a method to obtain extraordinary returns.

To be sure, there appear to be many examples where asset prices reached such 'bubble' levels that, at least in retrospect, it seems obvious that corrections were inevitable and that markets were inefficient. The housing bubble that peaked in 2002 is one example as is the Internet stock market bubble that peaked in 2000. And no one can reasonably argue that the prevailing prices in these examples were 'correct.' But the EMH does not require that prices be correct. Indeed, prices are always wrong. What EMH posits is that no one knows for sure whether the prices are too high or too low and that no obvious arbitrage possibilities exist to earn abnormal returns.

As discussed above, many analysts claimed during the 1990s that the stock market had reached bubble levels at prices substantially lower than were actually realized and many years before the actual peak. Similarly, the collapse of the housing bubble that led to the most severe world economic downturn since the Great Depression was not predicted by the monetary authorities. In the author's view, the correct conclusion is that we should be modest in our appraisal of how predictable asset prices really are. EMH remains an extremely useful hypothesis that is strongly supported by experience.

Abstract

Corporate governance research traditionally focused on how American corporations overcame potential pathologies created by the separation of ownership and control. Theorists described an array of mechanisms that oriented managers toward shareholder value, from incentive compensation and vigilant directors to a 'market for corporate control.' Research revealed, however, that top management retained wide discretion. Subsequent comparative and historical studies concluded that American-style corporate governance is only one of many possible formats. On the other hand, globalizing equity markets encourage common models for optimizing shareholder value and performance transparency, and at least partial convergence in the relations among managers, directors, and owners.

Theory and research on the relations among top managers, company directors, stockholders, and external contenders for corporate control experienced a remarkable flowering during the 1990s and 2000s. Early work addressed the central puzzle raised by the widespread separation of ownership and control among large American corporations, namely, why would any sensible person – much less thousands of them – invest their savings in businesses run by unaccountable professional managers? As Berle and Means (1932) framed the problem, those who ran such corporations would pursue 'prestige, power, or the gratification of professional zeal' in lieu of maximizing profits. Shareholders weakened by their fractionation could do little to stop them. Yet generations of individuals and financial institutions continued to invest in these firms. Why?

Resolving the Separation of Stock Ownership from Company Control

Answering this question led to the creation of a new theory of the firm that portrayed the public corporation as a 'nexus of contracts.' In this model, the managers of the corporation were disciplined to optimize shareholder value by an array of mechanisms, from incentive compensation and vigilant directors to an unforgiving 'market for corporate control.' Taken together, these devices worked to vouchsafe shareholder interests even when ownership was widely dispersed. Research in this tradition flourished as takeovers of underperforming firms in the United States became common and restive institutional investors made their influence known. Studies focused on assessing the effectiveness of such contrivances as governing boards dominated by outsiders, executive pay tied to stock performance, and susceptibility to hostile acquisition (Bebchuk and Weisbach, 2010; Gillan, 2006; Kang and Zardkoohi, 2005; Larcker and Tayan, 2011).

Three developments, however, expanded research on ownership and control beyond these mechanisms and beyond American business. The first was for investigators to view the governance structure of the firm – the set of devices that evolve within the firm to monitor managerial decision making – as an ensemble. Rather than regarding any particular aspect of the firm's structure as essential, researchers came to study them as complements or substitutes. Remuneration highly leveraged around share price, for instance, could act as a substitute for a vigilant board, and together they could really tighten the leash.

The second development was a growth of comparative and historical research that highlighted the idiosyncrasy of the American obsession with ownership and control. American-style corporate governance, aimed at 'solving' the problems created by the separation of ownership and control, came to be seen as only one of several feasible systems. Indeed, among some advanced economies with well-developed business enterprise, the problem needed no solving at all since the separation of ownership from control remained much the exception (Conger, 2009).

The third development was the articulation of a reflexive stance on the theory of ownership and control. While agency theory can be viewed as an empirical theory of the corporation, it also came to be considered a prescriptive theory, an explanation of not only what *is* but also a vision of what *could* or *should* be. Its influence on public policy debates in recent years is evident in the widespread rise of the rhetoric of shareholder value in the business press and executive suite (Davis, 2009; Lounsbury and Hirsch, 2010; Useem, 1996).

Shareholder Influence on Top Management and the Corporation

When ownership is widely dispersed, shareholders possess few direct devices to ensure their control – or at least their influence – on the company's direction and performance. This is the essence of the 'agency problem' identified by Berle and Means (1932), and it remains potentially potent among major US firms. Ownership is still relatively dispersed by global standards, although a small number of mutual funds and exchange traded funds have gathered relatively large ownership positions in hundreds of US corporations over the past 20 years (Davis, 2008), and by 2011 BlackRock (the world's largest asset manager) has become the largest

shareholder of one in five US corporations, including Citigroup, JP Morgan Chase, ExxonMobil, Chevron, AT&T, and Verizon.

Scattered shareholders in effect relinquish their control to directors whom they elect to serve as their agents in selecting and supervising top management. Dispersed holders can influence the firm only through trading shares and voting directors. They have no real voice in the selection of executives, or even who serves on the board. By one argument, shareholder inattention is in fact the only rational course for small shareholders since the cost of learning about the governance of the firm and mobilizing change is sure to be far overshadowed by the marginal and nonselective benefits of any resulting performance improvement. This problem of collective action could result in management unaccountability in some capital markets, as was evident in the financial crisis of 2008–09, but investors nonetheless rest more easy in the United States because of a well-developed set of mechanisms that have arisen to ensure share price maximization without overt investor control (Easterbrook and Fischel, 1991).

One forceful instrument for riveting attention on share price is the 'market for corporate control.' By hypothesis, a poorly run corporation suffers a depressed market valuation, and this opens an opportunity for outsiders with better management skills to acquire the firm at an implicit discount, oust top management, and rehabilitate the firm, thus restoring value to its long-suffering stockholders. Unwanted takeovers and their threats provide a potent mechanism to shock top managers who underserve shareholder interests; they know that executives generally find themselves on the street after an unfriendly takeover. The market for corporate control is thus one of the more visible hands of Darwinian discipline, weeding out poorly run firms and protecting shareholders from bad management (Manne, 1965). During the 1980s, more than one-quarter of the Fortune 500 largest industrials in the United States received takeover bids, although the risk of unwanted takeover declined dramatically after 1990.

Hostile takeovers are a blunt instrument for corporate control, and as a result, some US institutional investors moved toward more fine-grained methods of influence. Large pension funds, for example, often field shareholder proxy proposals for better governance. Evidence suggests that such efforts push targeted firms to improve their governance and thereby further open them further to investor influence (Karpoff, Unpublished). On the other hand, conflicts of interest often limit investor activism; for instance, mutual funds are more likely to vote with management on shareholder proposals to the extent that they manage corporate-sponsored pension plans, as many of the largest mutual funds do (Davis and Kim, 2007).

If hostile takeovers are often too blunt an instrument and shareholder activism too diffuse, stock analysts provide an intermediate form of shareholder influence on company behavior. Analysts investigate companies in order to render judgments on their prospects for future earnings and thus to estimate their appropriate valuation. In principle, the rewards go to the most accurate analysts, giving them incentives to act as corporate watchdogs (Useem, 1996). In practice, however, analysts often simply follow the lead of their peers rather than forming independent judgments (Rao et al., 2001).

Between Ownership and Control: Top Management

A handful of company executives make the defining decisions, whether to launch a new product, enter a promising region, or resist a tender offer. It is they who most directly control the fate of the firm. It is they who stand between corporate owners and company results (Cannella et al., 2008).

Firms often define their 'top' as no more than the seven or eight most senior officers. To much of the world beyond the company walls, however, top management is personified almost solely by the chief executive. Academic researchers had long been drawn to the same pinnacle of the pyramid, partly on the conceptual premise that the chief executive is the manager who really matters, and partly on the pragmatic ground that little is publicly available on anybody except the CEO.

We have also benefited from a long accumulation of work on chief executive family histories, educational pedigrees, and political identities, and we know as a result that their origins are diverse, credentials splendid, and instincts conservative. More contemporarily, we have learned much about their tangled relations with directors and investors as well. To know the CEO's personal rise and board ties is to anticipate much of the firm's strategic intent and performance promise. They are also a good predictor of the CEO's own fortunes. An elite MBA degree accelerates movement to the top, a wealthy background attracts outside directorships, and a hand-picked board enhances pay and perquisites (Stern and Westphal, 2010; Useem and Karabel, 1986).

The conceptual and pragmatic underpinnings for shining the light solely on the CEO as the fulcrum for ownership and control, however, have eroded in recent years, as companies redefined their operations and researchers reconceived their methods. At many companies, CEOs have fashioned teams among their top officers that meet frequently and resolve jointly, their vertical control giving way to lateral leadership. As a result, researchers expanded their field of view from the chief executive to the entire upper echelon. They applied fresh strategies, ranging from personal interviews to direct observation and Internet surveys, to acquire data on top managers other than the chief executive who now matter far more to company performance and stock analysts. A host of studies subsequently confirmed what many executives already appreciated. A better predictor of a company's performance than the chief executive's capability is the quality of the team that now runs the show (Cannella et al., 2008).

Yet even this widening of research attention beyond the chief executive has not broadened enough. Many companies have expanded the concept of top management to include one, two, or even 300 senior managers whose decisions have decisive bearing on firm performance. The concept of top management, then, has expanded in the minds of company managers and, to a lesser extent, academic researchers, from just the boss to the boss's team and now to the boss's court. The board of directors of many companies has also become a partner with management in leading the firm (Charan et al., forthcoming).

If shareholders are increasingly insistent that company directors require top managers to deliver steadily rising returns on their investments, their action is premised on a critical assumption that these top management teams do make the

difference. While the premise may seem intuitively obvious to those inhabiting this world, it is far from self-evident to those who study it. Observers diverge from the assumption of influential executives in two opposing directions, one viewing top managers as all powerful, others seeing them as all but powerless.

Vilfredo Pareto and kindred 'elite' theorists early articulated the all-powerful view, but C. Wright Mills captured it best for the United States in his classic work, *The Power Elite* (1956). Company executives, in his acid account, had joined with government officials and military commanders in an unholy alliance to exercise a commanding control over companies and the country. To the extent that top management is indeed all powerful, shareholders possess a silver bullet for righting whatever has gone wrong in a company: install new management.

For the community of management scholars, Pfeffer (1981) well articulated the opposite, all-*powerless* view with the contention that market and organizational constraints so tied top management's hands that it was much the captive, not a maker, of its own history. Production technologies and competitive frays in this view are far more determining of company results than the faceless executives who sit in their suites. It counts little who serves in top management, and, by extension, on the board. If top management is as powerless as the imagery suggests, investors seeking new management in response to poor performance are surely wasting their time.

Company executives do complain of a seeming helplessness at times, but almost anybody in working, consulting, or research contact with top managers reports just the opposite. Direct witnesses typically describe instead a commanding presence of top management, and they characterize its capabilities as making the difference between a company's success or failure. Investors themselves think otherwise as well. When companies announce executive succession, money managers and stock analysts are quick to place a price on the head of the newly arrived, and, depending on the personality, billions can be added to or subtracted from the company's capitalization. Ample evidence confirms that the chief executive does make a significant difference in company performance (Thomas, 1988).

The importance that investors and directors attribute to top management for growing their fortunes can also be seen in the ultimate punishment for failure to do so: dismissal. Whether the United States, Japan, or Germany, the likelihood of a CEO's exit in the wake of a stock free fall is increased by as much as half, and investors are often the engine behind the turnover. Study of Japanese companies stunned by a sharp reversal of fortune, for example, reveals that those whose top 10 shareholders control a major fraction of the firm's stock are more often than others to dismiss the president and replace directors (Kaplan, 1997).

Similarly, company boards are observed to reward successful executives far more generously than in the past. For each additional $1000 added to a company's value in 1980, directors on average provided their chief executive an extra $2.51. By 1990, the difference in their payments had risen to $3.64, and by 1994 to $5.29. Put differently, in 1980 the boards of companies ranked at the 90th percentile in performance gave their CEOs $1.4 million more than did boards whose firms ranked at the 10th percentile (in 1994 dollars). But by 1990, the boards had expanded that gap to $5.3 million and by 1994 to $9.2 million (Hall and Liebman, 1998).

Between Stockholders and Top Management: The Governing Board

If companies make semiconductors and concrete much the same way the world around, they organize their directors in almost as many ways as there are national economies. American boards tend to include only one or two insiders, while Japanese boards traditionally included only a handful of outsiders. German and Dutch governance is built around a two-tier governance structure, employees holding half of the upper-tier seats; British and Swiss governance is designed around a single-tier, management-dominated structure. Norway requires that two-fifths of board seats are held by women; Spain and the Netherlands have mandated the same. Some systems give formal voice to labor, others none: German law requires that labor representatives serve on the board, while French law places labor observers in the boardroom. American law mandates less, but US boards are now required to designate a lead director and to create an audit committee composed of independent nonexecutive directors (Charkham, 1994).

Yet such varieties in national practices may well diminish for two reasons. First, as equity markets internationalize, with companies seeking capital from all corners of the globe, investors predictably prefer relatively consistent director models that they believe will optimize shareholder value and performance transparency regardless of country, and investing has become far more crossborder in recent years. In 1970, foreign investors owned just 5% of Japanese shares, but by 2009 they held 26%; in the United Kingdom, foreign holdings rose from 7% of the share market in 1963 to 42% in 2008; in Korea, foreign ownership climbed from 5% in 1992 to 32% in 2009 (Federation of European Securities Exchanges, 2008). Moreover, thousands of firms have chosen to list their shares on foreign stock markets. By 2000, there were more foreign firms listed on Nasdaq and the New York Stock Exchange (NYSE) than there were German firms listed on the Deutsche Boerse.

International investors' mental models of what's right may not always be right, but that is beside the point. Consider the preference expressed by some institutional investors in the United States for a board chair who is not a sitting executive, believing that separation improves monitoring, a practice that is more common in the United Kingdom and elsewhere. Whatever the separatist penchant and however well it may have served some companies, research reveals that such a division creates no clear advantage for company performance (Baliga et al., 1996).

The diversity in directorship practices is likely to diminish, however, for a second, more factual reason. Certain practices do engender better performance, regardless of the setting, and as companies increasingly compete worldwide for customers and investors, they are likely to adopt what indeed does prove best. A case in point here is the number of directors on the board.

Research on teams' success suggests that bigger is not better when boards exceed 15 or 20 members. When the number of directors climbs far above middle range, the engagement of each diminishes, and so too does their capacity to work in unison. Studies of American and European firms reveal that smaller boards displayed stronger incentives for their chief executive, greater likelihood of dismissing an underperforming CEO, and larger market share and superior financial performance (Conyon and Peck, 1998).

It is not surprising, then, to see companies migrating worldwide toward smaller boards in search of improved performance. Directors in principle protect owner interests, direct company strategy, and select top management. In practice, they had concentrated more on executive selection and less on owner interests. But the rising power of investors has made for greater director focus on creating value and less coziness with top management. American and British directors, following the 'Anglo-Saxon' model, are already more focused on value than most. But directors in other economies can be expected to gravitate slowly toward the mantra of shareholder supremacy as well.

Shareholders, Directors, and Executives at the Table

With the rise of professional investors and their subjugation of national boundaries, those who occupy the executive suite and those who put them there are drawing far more research and policy attention, and justifiably so. In a bygone era when markets were more steady and predictable, when airline and telephone executives confidently knew what to expect next year, the identity of top management mattered less. When shareholders were far smaller and decidedly quieter, when airline and telephone directors comfortably enjoyed inconsequential board meetings, the composition of the governing body mattered less also. In recent years, however, all of this has changed in the United States and the United Kingdom with other economies close behind. As shareholders have sought to reclaim authority over what they owned, they have brought top management and company directors back in. Company strategy and financial results can no longer be understood without understanding the capabilities and organization of those most responsible for delivering them.

The Sarbanes–Oxley Act of 2002 in the United States and the introduction of stronger listing requirements by the NYSE in 2003 sought to enhance director capacity to exercise vigilance on behalf of shareholders. The Sarbanes–Oxley legislation requires that the board of publicly traded companies constitutes an audit committee of the board composed entirely of independent nonexecutive directors, and NYSE requires the same for the compensation and governance committee. The intention of their strengthening of the board committees in this way has been to improve their fiduciary oversight, and the behavioral results confirm the expected outcome. The revised stock-exchange listing requirements, for instance, have been found to significantly reduce executive compensation of listed companies – especially at firms that had least been subject to the pressures from institutional investors – implying that the new regulations served to improve the hands of directors in monitoring management (Chhaochharia and Grinstein, 2009). The Dodd–Frank Wall Street Reform and Consumer Protection Act of 2010 in the United States pointed in the same direction, giving shareholders greater say on executive compensation and requiring more independence for board compensation committees and their advisors.

The China Securities Regulatory Commission and Chinese regulations moved in the same direction since the Company Law of 1994 and Securities Law of 1998, as had the Securities and Exchange Board of India with its Clause 49 of 2004. Their thrust has been to strengthen the monitoring role of directors, though some legislative and regulatory provisions are found to have little of the intended impact (Brown and Caylor, 2009). Yet the effort to strengthen the directors' monitoring role could also have the unintended consequence of strengthening the directors' partnering role. By pressing directors to be stronger and more independent of management for the purpose of monitoring, government legislation and state regulations could at the same time be creating a platform for directors to seek a more active partnership with executives as well (Charan et al., forthcoming).

The market is no longer viewed as so impersonal, the company no longer so isolated. Ownership and financial decisions are embedded in a complex network of working relations among money managers, stock analysts, company directors, senior executives, and state regulators. Given the right combination of features, that lattice can yield high investment returns and robust national growth; the wrong amalgam, however, can lead instead to self-dealing, frozen form, and economic stagnation. The road ahead thus depends on how well researchers understand what control mechanisms and leadership styles work well both within national settings and across cultural divides, and on the extent that top managers, company directors, and stockholders learn and apply what is best.

Strain Theories and Crime

Sung Joon Jang, Baylor University, Waco, TX, USA
Robert Agnew, Emory University, Atlanta, GA, USA

Abstract

Strain theories state that certain strains or stressors lead to negative emotions, which create pressure for corrective action. Crime is one possible response, especially when people lack the ability to cope in a legal manner; the costs of criminal coping are low, and there is some disposition for criminal coping. Classic strain theories focus on one type of strain, the inability to achieve conventional success goals. Agnew's general strain theory (GST) focuses on a much broader range of strains and factors that influence the likelihood of criminal coping. Empirical support for GST has rejuvenated criminological research on strain.

Classic Strain Theories

Robert K. Merton (1938) developed the first major strain theory in criminology. He argues that *all* people in the United States are encouraged to strive for the cultural goal of monetary success. Lower-class individuals, however, are often prevented from achieving this goal through legitimate means. Their parents may fail to provide them with the skills and attitudes necessary for school success, they may live in communities with inferior schools, and their parents often lack the money to send them to college or set them up in business. As a consequence, lower-class individuals more often experience strain, with this strain being a function of the disjunction between their goals and the legitimate means for achieving them.

Merton states that there are several ways to cope with this strain, some of which involve crime. Individuals may attempt to achieve monetary success through illegitimate channels, such as theft, drug selling, and prostitution. They may strike out at others in their frustration. They may engage in drug use to alleviate their frustration. And they may reject the goal of monetary success and focus on the achievement of other goals, certain of which involve crime. Merton noted that most strained individuals live with their strain rather than cope through crime, and he went on to describe factors that influence the likelihood of criminal coping – such as the extent to which individuals are socialized to condemn crime.

Merton's theory led to the development of other strain theories, including that of his student, Albert Cohen. Cohen (1955) drew on Merton's theory to explain the origins of the lower-class, adolescent, male gangs that were common in the 1950s. Cohen states that lower-class individuals desire middle-class status, which includes both money and the respect of others. Lower-class people, however, have trouble achieving such status through legitimate channels. In particular, lower-class juveniles are often unprepared for school and are sometimes humiliated by their middle-class teachers and the middle-class students with whom they compete. But unlike monetary success, middle-class status is not a goal that can be readily achieved through illegitimate channels (i.e., one cannot steal middle-class status). As a result, certain lower-class adolescents cope with their strain in a different manner.

These adolescents develop an alternative status system in which they can successfully compete. Their hostility toward the middle class, among other things, leads them to value those things that the middle class rejects. The middle class values private property and polite behavior, for example, while these lower-class juveniles value theft and aggression. This alternative status system takes the form of juvenile gangs, with the gangs rejecting the cultural goal of middle-class status and substituting new, criminally oriented goals in its place. Researchers have questioned Cohen's argument that lower-class gangs fully reject conventional values and embrace crime (Agnew, 2000). But his argument that individuals sometimes adapt to strain by forming deviant subcultures appears to have some merit (Agnew, 2000).

Cloward and Ohlin (1960) developed yet another major version of strain theory. Like Cohen, they wanted to explain the formation and nature of lower-class juvenile gangs. And they too argue that the inability to achieve conventional success goals through legitimate channels contributes to the creation of gangs. But what most distinguishes their theory is the argument that any explanation of crime must consider not only the individual's opportunities to achieve conventional success goals but also the individual's illegitimate opportunities. That is, it must consider opportunities to engage in violence, theft, drug use and sales, and other crimes. Specifically, are individuals in contact with others who provide the skills, beliefs, and resources that facilitate these types of crime? This idea has found contemporary expression in routine opportunities and rational choice theories, which devote much attention to variation in the opportunities to engage in crime.

Despite their differences, the 'classic' strain theories of Merton, Cohen, and Cloward and Ohlin share in common the idea that strain involves the inability to achieve conventional success goals through legitimate means. These theories were perhaps the dominant theories of crime in the 1950s and 1960s. They also had a major impact on public policy, being an inspiration for the War on Poverty (Agnew, 2000). The War on Poverty was designed to make it easier for people to achieve material success through legal channels. It involved programs such as Project Headstart, a preschool enrichment program, and Job Corps, a jobs training program. But by the 1970s and 1980s, classic strain theory was being heavily criticized

and came close to being abandoned (e.g., Agnew, 2000; Agnew et al., 1996; Kornhauser, 1978).

Classic strain theory predicts that crime is concentrated in the lower classes, but many self-report studies in the 1960s and beyond found that the relationship between class and crime was weak. Relatedly, research revealed the existence of much white-collar and corporate crime. Furthermore, crime rapidly increased during the 1960s, despite increasing economic prosperity and a sustained effort to reduce poverty. Finally, several studies attempted to test classic strain theory by examining the relationship between aspirations or ideal goals and expectations or expected levels of goal achievement. These studies focused on educational and occupational goals, and argued that if classic strain theory is correct, crime should be highest among those with high aspirations but low expectations (i.e., those who desire a lot but expect little). Instead, crime was highest among those with low aspirations and expectations (e.g., Agnew, 2000; Agnew et al., 1996; Kornhauser, 1978).

Classic strain theory, however, has experienced a revival in recent years. It has been argued that the theory can explain higher class crime, since success goals are relative rather than absolute. That is, people look to others in their reference group when deciding what goals to pursue and evaluating their levels of goal achievement. Those in higher social classes often experience strain because they compare themselves to more privileged others (Passas and Agnew, 1997). This argument also helps explain the increase in crime during the 1960s. While many people improved their economic situation, others did not. These others may have experienced intense strain as they witnessed the economic progress of their friends and neighbors.

Finally, those studies examining the disjunction between aspirations and expectations were criticized for not focusing on economic goals (Agnew, 2000; Agnew et al., 1996; Passas and Agnew, 1997). Also, the inability to achieve aspirations or ideal goals was said to be a poor measure of strain. Aspirations have something of the utopian in them, so failure to achieve them does not generate much strain. More recent studies have found that dissatisfaction with one's monetary status and the experience of economic problems, such as trouble paying bills, are related to crime; these findings are supportive of classic strain theory (e.g., Agnew et al., 1996, 2008). Contemporary research on stress in psychology and sociology, however, suggested that the focus of classic strain theory on the inability to achieve conventional success goals was too narrow.

General Strain Theory

Building on his earlier works (Agnew, 1985, 1989), Agnew (1992) proposed a general strain theory (GST) of crime and delinquency, which focuses on a much broader range of strains. But like the classic strain theorists, he argued that these strains pressure individuals into engaging in crime through the negative emotions they generate. He also took an inclusive approach to other theories of crime, especially social control and social learning theories (Akers, 1985; Hirschi, 1969), by using their key concepts to help explain why some people are more likely than others to cope with strains through crime. Agnew's (1992) introduction of GST rejuvenated criminological research on strain, which had been out of favor for about two decades.

Foundation for a GST

Agnew's (1992) GST was built on his critical evaluations of Merton's (1938) classic strain theory and its revisions of Cohen (1955) and Cloward and Ohlin (1960). Presenting GST as another revision at the social psychological level, Agnew (1995a) argued that previous theories failed to realize the full potential or unique contribution that strain theory could make to the explanation of crime. To this end, Agnew suggested that strain theory should broadly define strain, place more explicit emphasis on the mediating role played by negative emotions, and identify a broader range of factors that influence the likelihood of criminal coping.

Strain, Negative Effect, and Conditioning Factors

Social control theory (Hirschi, 1969) explains crime in terms of the absence of positive relationships with conventional others, such as parents and teachers. Social learning theory (Akers, 1985) explains crime in terms of positive relationships with deviant others or at least those who reinforce deviance. GST, by contrast, posits that crime is a consequence of "negative relationships with others", or strain (Agnew, 1992: p. 48). Strain includes not only negative interpersonal relationships but also situations, conditions, and events that are objectively expected or subjectively perceived to be negative (e.g., parental abuse, chronic unemployment, homelessness, discrimination, and the immediate need for much money). Specifically, Agnew proposes three types of strain: strain as the actual or anticipated failure to achieve positively valued goals, which includes the classic conception of strain (i.e., the inability to achieve monetary goals); strain as the actual or anticipated removal of positively valued stimuli (e.g., the violent death of a close friend); and strain as the actual or anticipated presentation of negative stimuli (e.g., child abuse).

Next, GST proposes that strain generates negative effective states, such as anger and frustration, which create pressure for corrective action, including crime. This focus on negative effect helps distinguish GST from other theories. The effects of many types of strain on crime, such as child abuse and unemployment, can be explained using social learning and control theories (Agnew, 1995b). For example, child abuse provides the juvenile with a violent model, while unemployment weakens one's stake in conformity. But GST is the only theory to argue that these variables impact crime at least partly through the negative emotions they create (see Agnew, 2001, 2006 for other links between strain and crime).

GST focuses on the negative emotion of anger, which is said to energize individuals for action, reduce concern for the consequences of one's behavior, and create a desire for revenge. Agnew (1995b: p. 384) suggests that researchers should examine both "long-term or chronic anger and the frequency of angry episodes," that is, trait anger and state anger. State anger is a transitory emotional condition due to annoying or frustrating situations, whereas trait anger refers to an individual's disposition to perceive a range of situations as annoying or frustrating and respond to such situations with marked elevations in state anger. Thus, individuals with high levels of

trait anger are more likely to experience sustained elevation in state anger in reaction to strain than their peers with low levels of the trait. Because of this trait–state causality, while GST focuses on state anger, trait anger is also relevant to the theory. In addition, state anger can further be conceptualized and measured as 'situational anger,' produced by a particular strain that functions as a 'situational event' (Agnew, 1992: p. 60).

Although, for Agnew (1992: p. 59), anger is the "most critical emotional reaction for the purpose of the general strain theory", other negative emotions, such as depression and anxiety, are important as well. In fact, Agnew (1992) proposes that different types of negative emotions may lead to different crimes. For example, the inner-directed emotion of depression may be more conducive to internalized criminal acts, such as drug use, while the outer-directed emotion of anger may be more conducive to externalizing acts such as aggression.

Finally, while classic strain theories tend to be limited in explaining why not all strained individuals turn to crime for strain adaptation, Agnew (1992) addresses this issue by identifying a range of factors that affect the likelihood of criminal versus noncriminal coping. In particular, these factors affect a person's ability to engage in legal and criminal coping, costs and benefits in regard to criminal and legal coping, and disposition for criminal coping. They include both individual characteristics (e.g., self-efficacy) and environmental factors (e.g., social support).

Empirical Tests of GST

Early tests of GST generally provided empirical support for the theory. For example, Agnew and White (1992) found strain to have positive contemporaneous relationships with adolescent delinquency and drug use, while their lagged counterparts were significant only for delinquency, controlling for the previous measure of adolescent deviance. This first empirical test of GST was replicated by Paternoster and Mazerolle (1994), who found a positive strain–delinquency association to be not only direct but also indirect via control and social learning variables. Other researchers also reported positive (both direct and indirect) relationships between strain and crime based on longitudinal as well as cross-sectional data (Agnew, 1998; Hoffmann and Cerbone, 1999). While these findings were consistent with GST, the early studies were limited because of their omission of negative effect, and thus they could not attribute the positive association fully to GST (Agnew, 1995b).

On the other hand, Agnew (1985) found trait anger to explain most of the effects of strain on delinquency, whether confrontational (interpersonal aggression) or escapist (being late for or skipping class or school). Similarly, Brezina (1996) found strain to have significant effects on trait measures of resentment, anxiety, and depression as well as anger, while he did not examine the effects of the negative emotions on delinquency. In a later study, however, he found anger–delinquency as well as strain–anger associations to be positive (Brezina, 1998).

Other researchers examined state or situational as well as trait emotions because GST focuses on the former rather than the latter in explaining the criminogenic influence of strain, while recognizing the theoretical relevance of emotional traits to GST (Capowich et al., 2001; Mazerolle et al., 2000, 2003; Piquero and Sealock, 2000; Jang and Johnson, 2003; Aseltine et al., 2000; Broidy, 2001). Their findings together tend to show that state and, to a greater extent, situational emotions are more likely than trait emotions to mediate the influence of strain on criminal and deviant coping. In addition, Jang and Johnson (2003) tested the hypothesis about differential relationships between inner- and outer-directed negative emotions and deviance, and they reported supportive evidence: that is, anger was found to be more strongly associated with interpersonal aggression than drug use, while depression and anxiety were more strongly associated with drug use than aggression. In sum, prior research tends to show that negative emotions, however measured, are positively associated with both strain and crime, as GST posits.

Finally, studies tested the hypothesis that several factors condition the effects of strains and negative emotions on crime (Agnew and White, 1992; Paternoster and Mazerolle, 1994; Capowich et al., 2001; Aseltine et al., 2000). These studies examined conditioning variables such as self-esteem, self-efficacy, conventional bonding, and delinquent peer association. Despite some evidence that conditioning factors partly explain why strain does not always lead to crime, support for the hypothesized conditioning factors has been limited. This may be due to the difficulty of detecting interaction effects in survey research or the fact that researchers usually consider one conditioning factor at a time, with other factors controlled (Agnew, 2006). It may also be that individuals have to score high on several conditioning factors before criminal coping is likely (see Mazerolle and Maahs, 2000). Furthermore, researchers should examine other, understudied factors, like biopsychological traits (Agnew et al., 2002; Eitle and Taylor, 2011), religion (Jang and Johnson, 2003), and social support (Jang and Lyons, 2006).

Extensions of GST

After GST was introduced, it was extended to explain gender differences in crime (Broidy and Agnew, 1997), stability and change in crime over the life course (Agnew, 1997), community differences in crime (Agnew, 1999), and other patterns of offending (Agnew, 2006).

Gender and GST

Broidy and Agnew (1997) extended GST to explain gender differences in crime because the original GST does not offer an immediate explanation of the fact that, while males and females are not necessarily different in the amount of strain, females tend to report *higher* levels of negative emotions but *lower* levels of crime than males. To address the issue, they advanced three propositions. First, they propose that females are at least as strained as males but commit less crime partly because they are less likely than men to experience criminogenic types of strain. Second, they suggest, whereas females tend to report higher levels of anger than males, their anger is likely to be accompanied by less criminogenic emotions (e.g., fear, anxiety, guilt, and shame) and thus is mitigated by the concurrent nonangry emotions; and, as a result, females are less likely than males to turn to crime for strain adaptation. Third, they propose that females are less likely to turn to crime and deviance in response to strain partly because they are more likely to have prosocial

conditioning factors, such as coping skills and conventional social support.

Prior research tends to provide evidence of gender differences in types of strain (Agnew and Brezina, 1997; Hay, 2003; Mazerolle, 1998; Kaufman, 2009). For example, Jang (2007) found African-American women to be more likely to report strains related to physical health, interpersonal relations, and gender roles in the family, and less likely to mention racial and job strain than their male counterparts. Previous research also reports gender differences in the relationships between types of strains and emotional responses to strain (Broidy, 2001): for example, females' strains were more likely to be associated with inner-directed (e.g., depression and anxiety) than outer-directed emotions (e.g., anger), and vice versa was true for males' strains (Jang, 2007; Jang and Johnson, 2005). Finally, while the third proposition has been tested less often than the other two, Jang and Johnson (2005) found the distress-buffering effects of religiosity as a conditioning factor to be larger for women than men, which partly explains gender differences in deviant coping.

Life-Course Criminology and GST

Pointing out that life-course criminology was being dominated by control and social learning as well as biological and psychological theories, Agnew (1997, 2006) suggested that GST has a unique role in explaining stability and change in crime over the life course. First, GST posits that the individual traits of negative emotionality and low constraint explain the stability of crime. These traits increase exposure to criminogenic strains, contribute to negative emotional reactions, and foster criminal coping. For example, people high in negative emotionality (irritability) are more likely to elicit negative treatment from others, interpret such treatment as aversive (which increases subjective strain), blame others for adversity (which increases anger), and have limited conventional problem-solving skills (which increases the likelihood of crime being used as a coping strategy). These processes not only increase the probability of criminal coping but also help maintain and enhance the trait of negative emotionality, which in turn further stabilizes the pattern of criminal behavior over the life course.

Second, Agnew suggests that patterns of offending over the life course should at least roughly track levels of strain, negative effect, and conditioning factors. For example, according to GST, the 'age–crime curve' of delinquency, which increases, reaches a peak, and then decreases during adolescence and young adulthood, is likely to be in part a function of changes in the extent of one's negative relations with others (strain) and the tendency to interpret such relations as aversive, thereby experiencing anger and frustration, and cope with adversity through delinquency.

Although life-course research on GST is limited, findings tend to support the theory (Agnew, 1997, 2006). Hoffmann and Cerbone (1999) found a positive association between the number of stressful life events that adolescents experienced over time and the growth rate of delinquent involvement between early and middle adolescence, and the strain effect on the escalation of delinquency was found to not vary by potential conditioning factors, including self-efficacy and self-esteem. While not intended to test GST, Broidy et al.'s (2003) study revealed a pattern relevant to GST: chronic physical aggression during the elementary school years – a proxy of the aggressiveness trait – was positively associated with both violent and nonviolent forms of delinquency during adolescence. More recently, Eitle (2010) found changes in strain to be positively associated with changes in criminal activity among young adult males, which implies the effect of decreased strain on criminal desistance (see also Gunnison and Mazerolle, 2007); whereas Eitle et al. (2010) reported the criminogenic effect of strain over the life course, between early adolescence and young adulthood.

Macrolevel GST

Drawing on his original microlevel theory, Agnew (1999) proposed macrolevel GST (MGST) to explain community differences in crime, which have been studied based mostly on social disorganization and, to a lesser extent, subcultural deviance as well as relative deprivation theory. His proposed MGST model includes not only the key GST variables – strain, negative effect, and conditioning factors – at an aggregate level but also the exogenous variable of 'community characteristics,' like economic deprivation, inequality, overcrowding, high population mobility, and a high percentage of nonwhite members. In addition to increasing community-level strain, these characteristics tend to contribute to the selection and retention of strained individuals because they, especially those who are economically strained, are likely to move into deprived communities where they can afford to live and their migration would meet little resistance. Thus, the community characteristics in the MGST model help control for self-selection bias as well as specify the source of community strain.

Community strain includes all three types of strain in GST: the failure to achieve positively valued goals, the loss of positive stimuli, and the presentation of negative stimuli (e.g., goal blockage, family disruption, incivilities, relative deprivation, and frequent interactions with angry or frustrated people). MGST posits that community strain generates community-level (or aggregate) negative effect, which in turn increases community crime rates, while conditioning factors moderate the positive associations between community strain and negative effect and between community negative effect and crime rate. It also posits that community crime tends to increase community negative effect, proposing reciprocal causal relationships between the two.

Research on MGST has been limited partly because data to test the theory are relatively unavailable. Specifically, unlike the measures of community characteristics, community strain, as well as community crime that can be drawn from the US Census and FBI Uniform Crime Reports data, those of community negative effect and conditioning factors are not easy to construct because it requires aggregating individual-level data on those variables from a survey conducted in multiple community-level units, each of which includes a large enough number of respondents for the aggregation. Despite this operational challenge, several studies have been conducted to test MGST.

Based on national survey data, Brezina et al. (2001) found a positive association between school-level anger among students and fighting or arguing with other students, as MGST posits. Next, although failing to include community negative effect, Warner and Fowler (2003) reported not only positive associations between the Census-based variables of deprived neighborhood characteristics and aggregated measures of

experienced and vicarious strain (violent behaviors witnessed or heard in the neighborhood) but also an aggregated measure of social support and social capital conditioning the effects of the strain on violence. Finally, although not intended to test MGST, Stockdale et al. (2007) found community strain to be positively associated with alcohol, drug, and mental health disorders, and the positive association was conditioned by community-level social support.

Looking Back and Looking Forward

Based on the first 10–15 years of its empirical tests, Agnew (2001, 2006) critically assessed GST for further conceptual specifications and theoretical elaboration. First, distinguishing between objective and subjective strains, he proposed strains to be the most criminogenic when they (1) are seen as unjust, (2) are high in magnitude, (3) are associated with low social control, and (4) create some pressure or incentive for criminal coping. Examples include child abuse and neglect, abusive peer or marital relations, criminal victimization, and racial and gender discrimination. Agnew (2002) further divided strains into experienced, vicarious, and anticipated strains, arguing that while experienced strains should be most strongly related to crime, vicarious and anticipated strains may contribute to crime in some circumstances (e.g., Jang and Rhodes, 2012).

Second, Agnew calls for more research examining understudied types of strains (e.g., work in the secondary labor market, and discrimination), the 'causal' effect of strain based on panel data with a short interval, and indirect effects of strains on crime via social control, social learning, and personality variables. Third, he also points out a relative lack of research not only on emotional states (as opposed to traits) but also on other emotions than anger. Fourth, in response to the limited evidence for conditioning factors, Agnew suggests that studies based on other methods than survey (e.g., experimental, vignette, and observational studies) should be conducted given the difficulty of detecting interaction effects with survey data. In addition, he suggests that researchers should examine conditioning factors in combination rather than in isolation from one another.

Finally, Agnew stresses that GST is more than a microlevel theory explaining individual differences in crime, and thus needs to be applied to account for group (other than gender) or community differences in crime. For example, GST can shed light on racial and ethnic differences in crime (e.g., Kaufman et al., 2008). Furthermore, research opportunities for cross-national studies to extend GST to account for societal or cultural differences in crime are another area where more research is needed (see Agnew, 2006). These opportunities and the topics discussed here for future research confirm that GST is still "a work in progress" (Agnew, 2006: p. 202).

Strategic Adaptation

Torben J Andersen, Center for Global Strategic Responsiveness, Copenhagen Business School, Frederiksberg, Denmark

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article provides an overview of theoretical contributions that have influenced the discourse around strategic adaptation including contingency perspectives, strategic fit reasoning, decision structure, information processing, corporate entrepreneurship, and strategy process. The related concepts of strategic renewal, dynamic managerial capabilities, dynamic capabilities, and strategic response capabilities are discussed and contextualized against strategic responsiveness. The insights derived from this article are used to outline the contours of a dynamic process of strategic adaptation. This model incorporates elements of central strategizing, autonomous entrepreneurial behavior, interactive information processing, and open communication systems that enhance the organization's ability to observe exogenous changes and respond effectively to them.

Introduction

The topic of strategic adaptation is as old as the strategy field and can most likely be traced in the earlier management literature. The idea that organizations must be able to develop strategies that suit the circumstances seems so obvious that we hardly think about it. With that also follows that the ability to adapt the strategy as the surrounding business environment changes is an essential managerial concern. The common view is that managers try to develop a proper strategy for the environmental context and design an organizational structure to match it. When the environmental conditions change then the strategy and structure will also have to be adapted accordingly. As argued by Ansoff and Brandenburg (1971: B-706): "Rapid changes in customer needs and product-process technologies require organizations that are flexible and responsive." Therefore, it is hardly surprising that strategic management in its essence relates to the process of adapting the strategy to dynamic changes in the surrounding environment.

Substantial energy has been devoted to uncover how the business environment is changing. It has been characterized as, e.g., dynamic, turbulent, and hypercompetitive with frequent technological changes, shorter product cycles, and ongoing innovation that continue to challenge existing competitive advantages (Thomas and D'Aveni, 2009). The environment is becoming more unpredictable and calls for strategic response capabilities (Bettis and Hitt, 1995), adaptive capabilities (Volberda, 1996), and dynamic capabilities (Teece et al., 1997; Teece, 2007) to facilitate adaptation to ongoing changes.

So much has been written about this theme over the years that it is literally impossible to cover it all comprehensively in a single article. It might also be rather futile to give an encyclopedic account of the entire literature since much of the discourse revolves around the same basic ideas but often with new labels and under new headings. The area subscribes substantially to differentiating concepts and terminologies that can lead into something of a semantic quagmire. Nonetheless, there are traces of development in central elements of strategic adaptation that seems to evolve around the firm's ability to respond to change. This article will try to uncover these subtle, possibly subjective, observations more or less in chronological order and use them to outline an evolutionary path that may be underway.

The article will first discuss the contingency perspective that implicitly promotes an underlying idea about fit. Then corporate entrepreneurship is presented as driver of strategic renewal and adaptation. Finally, the more recent concepts of dynamic managerial capabilities, dynamic capabilities, and strategic responsiveness are used to theorize about the dynamic process of strategic adaptation.

Environmental Contingency and Fit Perspectives

The effectiveness of managerial decisions and actions depends on the situation and the circumstances around them including the conditions of the firm's internal and external environment. This is an underlying premise of contingency theory. However, the early focus on planning processes in strategy-paid lip service to this premise at least to some extent, which led to a move away from strategy process toward an emphasis on strategy content and the environmental conditions that affect strategic choices (Hofer, 1975). This drive toward a focus on content considered organizational characteristics and environmental circumstances that could be "of major importance in determining the content of specific business strategies" (Hofer, 1975: 792–793). These included, for example, economic, demographic, social, and political/legal conditions all of which today are recognized as essential elements of an environmental analysis.

In considering the effect of environmental conditions was also an implicit concern for the ability to deal with external changes since the environment by experience is not stable in the longer run. In fact, it can be considered of the uttermost importance and Chakravarthy (1982: 35) went as far as arguing that "the essence of management is coping with change." He conceived of three types of change that would require three states of adaptation: an unstable, a stable, and a neutral state. In the unstable state the firm buffers itself from environmental events. In a stable state the firm operates under benign conditions and can react to changes. In a neutral state the firm anticipates the changes, absorbs them as they arise, and adapts

the organization to accommodate the new conditions (Chakravarthy, 1982).

This analysis assumes a better match between the adaptive state and choices between mechanistic and organic structures. An organic structure with little formality and much decentralization and information-sharing works better in a neutral state where the organization has a high degree of adaptability. It might not be as simple though because the strategic choices made between organic and mechanistic structures can be achieved in many different ways (equifinality) and the environment can be more or less forgiving of the underlying decisions. That is, the strategic choice and the environmental pressure constitute two distinct dimensions that can frame different adaptation typologies (Hrebiniak and Joyce, 1985). Hence, conscious structural choices can achieve adaptation either by design or by chance, or adaptation can be constrained if the firm is not simply selected out by competitive forces.

The adaptation contingencies and the implied performance effects are often taken for granted as automatic outcomes. As Drazin and Van de Ven (1985: 514) state so eloquently "it appears that our concepts of fit are drawn from a general and often implicit pool of domain assumptions and methodological conventions." The core argument is that organizational structure and processes should fit the environmental context for the firm to survive. But fit is not a clear-cut concept and can be seen from at least three increasingly complex views: (1) congruence between structure and context, (2) match between pair wise structure–context factors, and (3) consistency between multiple contingencies and multiple structural elements. This alludes to the fact that dealing with turbulent environments requires more complex responsive organizational structures to achieve high performance (Drazin and Van de Ven, 1985).

Structural change is not just an automatic response but rather evolves from a structural adjustment process of regaining fit as the environment changes (Donaldson, 1987). Contingency determinism assumes that changes in external conditions lead to changes in the structural variables directly whereas structural adjustment alludes to an underlying adjustment process. Shifts in environmental contingencies will create a disequilibrium that leads to declining effectiveness. This in turn will create internal pressures for change that eventually drive actions of structural adaptation aimed at regaining fit.

Strategic Fit

The concept of fit between the environment, strategy, and the supportive organizational structure is referred to as strategic fit where performance is seen as partially determined by a match between firm strategy, structure, and the environment. In the words of Jennings and Seaman (1994: 461): "organizations having an optimal strategy-structure match will give higher performance." It is formalized in strategic fit theory (Fiegenbaum et al., 1996) arguing that higher performance is achieved when the strategy content and the organizational structure are aligned with the external conditions. Hence, dynamic environments require adaptive firms associated with an organic structure and they perform better if they pursue a prospector strategy at the same time (Jennings and Seaman, 1994). In contrast, nonadaptive firms in more stable environments perform better when they have a mechanistic structure and follow a defender strategy.

The strategic fit concept can be extended to consider aspects of corporate culture where proper aims and values are seen as equally important. Scholz (1987: 78) refers to strategic fit as the situations "in which all the internal and external elements relevant for a company are in line with each other and with the corporate strategy." He argues that this entails *intrastrategy* fit where the strategy elements are consistent, *intrasystem* fit with congruence between structural elements, *strategy-system* fit for consistency between strategy and structural elements, and *internal–external* fit where the structural system is tailored to fit the environment. However, corporate culture forms the human behaviors and intensions in strategic actions and, therefore, should also suit the chosen strategy. Scholz (1987: 80) refers to corporate culture as "the implicit, invisible, intrinsic, and informal consciousness of the organization which guides the behavior of individuals." He further argues that it can be helpful to aggregate various dimensions of corporate culture to form generic cultural types and use these typologies to assess whether the culture is a good match to the strategy (Scholz, 1987).

Organizational Perspectives

The vast literature on new organizational forms points toward a need for responsive decision structures. A centralized structure confines decisions to top management whereas decentralization authorizes managers at lower levels to take responsive initiatives. The structural solution to deal with increasing information flows and pressures from organizational dependencies seems to be a move of decision power down the organization closer to where the relevant information is located (Child and McGrath, 2001; Volberda, 1996). Hence, a broad literature advocates decentralization under pervasive uncertainty.

It is generally recognized that adaptive strategy-making also needs integrative organizational features. Effective organizations engage in central integrative processes with dispersed decisions embedded in more rigid organizational structures (Hill et al., 2000). The real challenge, therefore, seems to be to create the right combination of strategic control features and experimentation within the organization.

Adaptive Organizations

In empirical studies of strategy development patterns, Miller and Friesen (1980) observed that extreme periods of stable momentum and dramatic revolution seem to interchange reflecting a certain resistance to reverse strategic direction. They further noted that continuous changes are more common than fundamental reversals and that the interdependencies between structural variables lead to ongoing adjustments when the smaller adjustments are carried out (Miller and Friesen, 1980).

Organizations seem to go through major epochs of rather stable strategy–structure constellations broken off by shorter periods of quantum change and strategic reorientation (Mintzberg and Waters, 1982). This phenomenon often referred to as punctuated equilibrium consists of relatively long periods of equilibrium intercepted by shorter periods of revolutionary

adaptations. The punctuation of stable periods can be caused by major environmental changes, such as, the emergence of new disruptive technologies (Romanelli and Tushman, 1994). Hence, periods of revolutionary adaptation seems to occur when significant changes happen in the environment that disrupts the prior conditions for a structural equilibrium and calls for new structure forms that can respond to those changes.

This may speak for advantages of continuous changes that can modify the strategy–structure relationship on an interdependent basis as the organization gradually adapts to accommodate ongoing changes in the environment. To this effect Mintzberg and Waters (1985) consider a more responsive low-level emergent approach to strategy making in conjunction with a high-level intended planning approach. They argue that emergent strategy means that management is "open, flexible and responsive, in other words, willing to learn" and that "strategy formation walks on two feet, one deliberate, the other emergent" (Mintzberg and Waters, 1985: 271). This dual approach may enable top management to direct strategic actions toward realization of intended outcomes while at the same time leaving room for organizational members to respond to the environmental changes as they unfold.

A population ecology perspective conceive of internal and external selection mechanisms as low-level business initiatives prove their commercial viability and eventually may grow into corporate business saviors when market changes may require a new strategic focus. Burgelman (1991: 240) argue that these "strategic initiatives come about, in part, as the result of individual strategists seeking expression of their special skills and career advancement through the pursuit of different types of strategic initiatives." A number of internal mechanisms, including decision rules, hurdle rates, behavioral norms, etc., determine the advancement of initiatives that can develop into viable businesses. The low-level strategic initiatives can be venues to shape technologies and products that address new customers while developing essential capabilities that can support future adaptive moves. Hence, the process is a way to obtain strategic renewal through internal experimentation and selection.

Various studies illustrate the significance of decentralized initiatives developed within the organization as the source of opportunities that can have potential strategic implications (Burgelman, 1988). The so-called Bower–Burgelman process model (Burgelman, 1996) depicts strategy making as a function of business initiatives pursued by low-level managers that, if they are successful, can be promoted for consideration as part of the official corporate strategy. Top management influences strategy by formulating policies and organizing the structure, processes, and systems that support the progression of business initiatives. Hence, responsive strategy making relies on effective decision processes and communication channels between hierarchical levels to determine which initiatives may successfully adjust the corporate strategy.

Corporate Entrepreneurship

Entrepreneurial initiatives try to exploit opportunities and create capabilities that respond to environmental developments where "corporate entrepreneurial initiatives are depicted as casually adjacent to new and more favorable strategic positions" (Garrett and Covin, 2007). Entrepreneurial opportunities can be pursued as intended and emergent initiatives where strategic goals are targeted while leaving room for new relevant business leads. The ability to seize new markets and capitalize on technology development to gain adapted strategic positions requires leadership support, resource availability, and decision-making autonomy.

If the firm maintains a reasonable fit between the organization and the environment it will perform well and generate slack resources (Chakravarthy, 1982), which in turn provides discretionary means for ongoing entrepreneurial initiatives. That is, an entrepreneurial model of strategic adaptation can lead in "a virtuous circle to the generation of rents that make the pursuit of future entrepreneurial initiatives possible" (Garrett and Covin, 2007: 11). Hence, strategic adaptation can be seen as the outcome of entrepreneurial initiatives that continuously pursue new opportunities where new resources are deployed "according to imperatives created by changing environmental conditions" (Garrett and Covin, 2007: 20–21; Figure 1).

Figure 1 An entrepreneurial emergent model for strategic adaptation. Note: Inspired by Garrett, R.P., Covin, J.G., 2007. A model of corporate entrepreneurship as a strategic adaptation mechanism. Advances in Entrepreneurship, Firm Emergence and Growth 10, 9–31.

The gradual molding of entrepreneurial initiatives resonates with the concept of effectuation as entrepreneurial processes that "take a set of means as given and focus on selecting between possible effects that can be created with that set of means" (Sarasvathy, 2001: 245). According to this logic entrepreneurial initiatives use available resources and competencies to discover emergent strategic opportunities at acceptable risks and thereby generate low-cost exploratory search processes for adaptive strategic ventures. In line with the prior organization theoretical arguments, the effectuation approach is also hypothesized to "build strong participatory cultures, rather than hierarchical, procedures-based ones" (Sarasvathy, 2001: 261).

Strategic Renewal and Dynamic Capabilities

Managers differ in their ability to deal with change and, therefore, approach adaptive decisions differently, which affects the strategic outcomes. These dynamic managerial capabilities are defined as "the capabilities with which managers build, integrate, and reconfigure organizational resources and competences" (Adner and Helfat, 2003: 1020). This is not far from the definition of dynamic capabilities as "the capacity of an organization to purposefully create, extend, or modify its resource base" (Helfat et al., 2007: 4). However, the former is focused on the top management echelon whereas the latter looks more into the firm-level mechanisms that may involve a broader set of organizational constituents. Asset orchestration and the ability to coordinate resource decisions are considered central as the "fit between resource investments and their means of deployment is important for firm performance" (Sirmon and Hitt, 2009: 1376). Hence, the reconfiguration of resources is an essential element of strategic renewal and dynamic (managerial) capabilities.

Strategic renewal includes "the process, content, and outcome of refreshment or replacement of attributes of an organization that has the potential to substantially affect its long-term prospects" (Agerwal and Helfat, 2009: 282). There are fundamentally two types of transformation: discontinuous and incremental renewal. Incremental strategic renewal is conceived as a more proactive approach that "enable firms to cope with changes in the external environment as they take shape, and thereby reduce the need for a much larger and more difficult transformation later on" (Agerwal and Helfat, 2009: 283). Both incremental continuous renewal and discontinuous transformations can eventually contribute to significant organizational changes as "a series of small incremental changes can accumulate into a much larger change when viewed over a longer time span" (Agerwal and Helfat, 2009: 284).

The new competitive landscape characterized by increasing uncertainty and a decreasing ability to forecast developments within ambiguous industry borders calls for strategic response capabilities (e.g., Bettis and Hitt, 1995). Effective dynamic responses must incorporate the ability to sense the environmental changes, find proper responses to the changes, and reorganize available resources to execute the responses. This calls for dispersion of decision power to local decision nodes as "a flatter hierarchy reduces both transmission time and the distortion as information moves up and down the hierarchy, and, thus, improves performance" (Bettis and Hitt, 1995: 16).

Along the same lines, Teece et al. (1997) argue that successful firms demonstrate timely innovation where internal and external competences are coordinated and redeployed in effective responses. The underlying theme is that firm competencies must be renewed to remain congruent with a changing environment and both internal and external resources and competencies must be reconfigured to match the changing conditions. On this basis they define dynamic capabilities "as the firm's ability to integrate, build, and reconfigure internal and external competences to address rapidly changing environments" (Teece et al., 1997: 516).

A more formalized conceptualization of the dynamic capabilities approach comprises three elemental functions. First, the ability to *sense* ongoing changes and identify new opportunities and threats in the evolving business environment. Second, the ability to *seize* opportunities in new products, processes, and services and develop them into viable business propositions. Third, the ability to *reconfigure* and recombine resources and competences into modified organizational structures that respond to market and technology changes (Teece, 2007).

Responsive Strategy Conduct

The strategy conduct approach relates to managerial decisions but differs from the contingency perspective. It does not try to explain management behavior but attempts to show how good responsive practices can lead to better strategic adaptation and favorable outcomes. The underlying idea is to develop response capabilities that allow the firm to retain strategic fit by assessing external changes accurately, formulating appropriate responses, and reconfiguring internal resources in effective responses. "We will refer to this bundle of capabilities to assess the environment, identify firm resources, and mobilize them in effective responsive actions (achieving strategic fit over time) as strategic responsiveness" (Andersen et al., 2007: 411).

The ability to adapt to environmental change may affect organizational performance as good responsive management practices can lead to higher returns and lower variation of returns at the same time. A simple model of strategic responsiveness related to the organization's ability to assess environmental conditions, mobilize available resources, and implement responsive actions that adapt the organization toward a better strategic fit shows how this can come about.

The model assumes that a firm's resource endowment can achieve an optimal performance K, if it applies these resources effectively to obtain perfect strategic fit. If a firm is unable to assess the environment and respond effectively to environmental changes there will be a strategic mismatch and performance will be below K. If poor responsiveness leads to wide discrepancies between the firm's position compared to the environment, performance will be particularly low. The performance function of a given firm in period t is then expressed as:

$$R_t = K - b|c_t - d_t|^a$$

Here c_t is interpreted as a key environmental parameter whereas d_t is a central structural dimension in the firm corresponding to its chosen position with respect to parameter c at time t. Managers in the firm observe environmental changes from period to period, identify solutions based on available resources, and deploy them in responses that try to move the firm closer to the environment. The coefficients (a, b) determine how severe the effect of a misfit will be. If the firm is unable to match the environment, performance suffers in proportion to the size of the misfit.

To achieve optimal performance a firm must be able to match d_t to c_t at all times, but in reality firms cannot always achieve a perfect fit, due to uncertainty, imprecise foresight, judgmental errors, biased information, etc. Hence, one must expect that firms have different response capabilities with some firms more likely to reach fit than others. The performance function together with the heterogeneity assumption leads responsive firms to have higher profitability and lower variance in profitability, and vice versa for nonresponsive firms, which is expressed in an inverse risk-return relationship (Andersen et al., 2007). That is, responsive firms that can adapt effectively to obtain better strategic fit will gain higher performance outcomes as well as they will achieve them with lower variation in outcomes over time.

Responsive Strategy Making

How do we synthesize the preceding insights derived from different theoretical angles toward describing a responsive strategy-making process? There seems to be general agreement about a need to decentralize decisions to induce entrepreneurial behavior and responsive initiatives at lower hierarchical levels. There seems to be good arguments for incremental responses to achieve continuous adaptation of strategy and structural parameters as the environmental context evolves. It further projects more complex hybrid structural forms that combine elements of intended planning and strategic emergence. This suggests that a combination of analytics-based strategizing and autonomy to pursue entrepreneurial initiatives together with interactive exchanges of information in open communication systems can improve environmental sensing and the ability to identify new opportunities for strategic responses.

Strategic emergence relates to decentralized, or autonomous, initiatives where strategy is shaped by experimentation with new opportunities pursued in actions taken at lower hierarchical levels (Andersen, 2004; Burgelman, 1988). The dispersion of decision power allows low-level managers to take actions in response to environmental changes they identify and thereby experiment with alternative business solutions. To avoid too divergent experimentation a more complete model incorporates intended planning modes with interactive management information systems levered by intraorganizational communication (**Figure 2**).

While it is often assumed that top management has more updated information about organizational performance, it can also be argued that frontline employees that learn from daily transactions have a good immediate sense of the effectiveness of firm capabilities. Their hands-on experience from the ongoing dealings with major stakeholders gives them updated information to assess current competencies and their effect on performance (Hallin et al., 2013). This unique information can be collected and channeled in concise form as updated inputs to the strategic decision processes, which can accommodate faster and more accurate responses to incremental environmental changes.

The combination of decentralized experimentation and central strategic reasoning constitutes the central building blocks of a responsive organization. In this organization current observations and experiential insights gained by operating managers and frontline employees are linked to the forward-looking planning that is considered and articulated around the top management team. This identifies a responsive organization that is able to observe and react to frequent and often abrupt environmental changes and adapt organizational activities to a gradually changing reality (Andersen and Fredens, 2011). This perspective highlights the significance of dynamic interaction between the operational managers involved in the execution of business activities and the top managers involved in forward-looking long-term strategy discussions. Hence, the firm's strategic considerations are updated and revised partially based on experiential insights from autonomous initiatives and, therefore, provide more

Figure 2 An interactive long-term responsive strategic adaptation model. Note: Inspired by Andersen, T.J., 2013. Short Introduction to Strategic Management. Cambridge University Press, Cambridge, UK.

updated and accurate environmental sensing for better and more responsive strategic decisions.

The decentralized structure that allows local experimentation may uncover new business opportunities (Burgelman, 1996; Burgelman and Grove, 2007) that can be fed into the periodic strategy deliberations in the long-term strategic planning process. Hence, strategic management and information processing can support updated forward-looking evaluations of opportunities uncovered by insights gained from autonomous initiatives. "That is, an integrative structure circumscribed by dispersed actions can be construed as a cohesive dynamic system where the elemental parts constitute the organization's response capabilities" (Andersen and Fredens, 2011).

Discussion and Conclusion

The preceding overview of article linked to the strategic adaptation topic has uncovered a considerable legacy of contributions forming different aspects of the concept although not necessarily providing a clear depiction of the adaptive strategy processes. The ability to create strategic fit and retain it as the environment changes is a central theoretical argument for strategic adaptation and the importance ascribed to the concept is its necessity for survival and the fact that it simply pays off to adapt. This is because the highest returns are awarded to those firms that can fulfill the changing customer needs, technological capabilities, operational competencies, and so forth at all times. The underlying processes of adapting the internal strategy-structure system to fit the changing external conditions are carried out through relatively complex adjustment mechanisms. Strategic fit is not achieved as an automatic reaction.

The strategic adaptation process is typically a piecemeal encounter where incremental adjustments in local entities lead to coevolutionary adjustments in other related parts of the organization. Continuous changes are more common than revolutionary changes but may nonetheless lead to substantial movements in strategy over time as many small steps add up. Adapting things incrementally is a way to avoid dramatic need-based and forced change scenarios. The continuous incremental changes can come about in the form of autonomous low-level initiatives pursuing entrepreneurial opportunities that subsequently may lead the way toward new strategic positions. Adhering to a long-term strategy process at the same time gives direction toward intended goals and coordinates strategic actions.

A formal model of strategic responsiveness and adaptation can show how firms will gain higher returns with lower variability in returns when they adapt particularly well to environmental changes and consistently obtain superior strategic fit. This inverse risk-return effect is particularly pronounced in dynamic industries where change is frequent and substantial so it is more difficult to assess and adapt to the changing conditions. This shows a need to further elaborate on the core strategic response capabilities as important elements of effective strategic management processes. Here the ability to sense environmental changes and reconfigure competencies around effective responses to the changing environment is essential.

A suggested model for strategic adaptation combines intended long-term strategy with emergent strategy making in the form of autonomous initiatives experimenting with strategic opportunities for changing conditions. The structure incorporates updated information processing and open communication to facilitate interaction and mutual adjustments between the intended and emergent processes. This integrative structure comprised by forward-looking strategic reasoning and entrepreneurial experimentation constitutes a dynamic responsive system.

Strategic Management

Robert A Burgelman, Stanford University, Stanford, CA, USA

Abstract

Strategic management has become a well-established, though still somewhat fragmented, academic discipline. Two of its theoretical foundations – the strategic positioning view and the resource-based view – together with an integrative view on strategy formulation and implementation are combined into one conceptual framework. Similarly, strategizing and economizing are combined into a conceptual framework that integrates external-oriented perceived value (focused on strategizing) and internal-oriented delivered cost (focused on economizing) to provide further insight into the performance challenges facing strategic management. Finally, a framework is constructed that integrates four models of the strategy-making process proposed in different academic literature relevant for strategic management.

Genesis and Development

The academic field of strategic management grew out of the earlier pedagogical field of business policy, which was conceptualized as an integrative capstone course to be taught at the end of the business school curriculum to teach students how to integrate the various functional areas, but was not considered a field of research in its own right or a broader scientific discipline (Schendel and Hofer, 1979). In the context of becoming viewed as a new academic field, strategic management was initially defined as "…a process that deals with the entrepreneurial work of the organization, with organizational renewal and growth, and more particularly, with developing and utilizing strategy which is to guide the organization's operations" (Schendel and Hofer, 1979: 11). The creation, in 1982, of the Strategic Management Society provided scholars of the new academic field with an institutional home, and the yearly Strategic Management Society Conference and the establishment of the *Strategic Management Journal* (*SMJ*) offered them an outlet for their research.

By the late 1980s, the strategic management field had gained enough momentum to motivate organizing a second conference in Napa, California, in 1991 to examine progress made since the 1977 conference in Pittsburgh, Pennsylvania, and to provide further directions for the development of the field. Synthesizing the insights from the conference papers and discussions into book form, the organizers (R. Rumelt, D. Schendel, and D. Teece) identified four key issues, translated into research questions, that could be helpful in defining the field of strategic management, its boundaries as they existed at the time, its concerns, and how the field could make a contribution to the practice of management: (1) How do firms behave? (2) Why are firms different? (3) What is the function of, or value added by, the headquarters unit in a multibusiness firm? and (4) What determines the success or failure of the firm in international competition? (Rumelt et al., 1994: 2). By the time they were able to publish their book 3 years after the conference, the organizers realized they had failed to pay enough attention to the nature of what they call the 'policy process' – the strategy-making process – and to several other important questions (1994, Afterword). In other words, it had become clear that there simply was no way to guide scholars in advance to what would be the important contributions to the strategic management field.

By the mid-2000s, *SMJ* had become a well-respected A-level academic journal and the Strategic Management Society Conference every year attracted some 1000 academics, consultants, and business leaders (the ABCs) from all over the world. Yet the burgeoning new academic field was still viewed by many as fragmented and lacking of a coherent identity. As the result of empirically identifying the common substantive core of the field and the implicit consensus among its diverse scholars about what constitutes the field's coherence and identity, Nag, Hambrick, and Chen were able to arrive at a new definition of the field: "The field of strategic management deals with the major intended and emergent initiatives taken by general managers on behalf of owners, involving utilization of resources, to enhance the performance of firms in their external environments" (2007: 944). The researchers realized that this definition of the field was in many ways too restrictive, but suggested that "…the greatest benefit of having this definition is that it allows strategic management scholars to frame the debate about what they want the field to become, or how they want to change it" (2007: 951).

Some Theoretical Foundations

Soon after the initial formation of the strategic management field, Porter (1980) appeared on the scene to provide the inchoate new field with a solid foundation rooted in the economics of industrial organization. Porter's seminal discussion of the importance of 'strategic position' and 'generic strategy' for competitive advantage stimulated the development of the 'positional school' in the strategic management literature (for an updated view, see Stonehouse and Snowdon, 2007).

Shortly after Porter's breakthrough contribution, Wernerfelt's (1984) articulation of the so-called resource-based view offered an alternative to the 'position-based view' of competitive advantage. In this view, resources are broadly defined to encompass technical, commercial, as well as knowledge, administrative and cultural factors. Some of the

foci of the resource-based view are on the competitive advantages that may derive from resource heterogeneity among firms and on the sustainability of resource-based advantages (for a critical review, see Kraaijenbrink et al., 2010). In an important sense, the resource-based view also relates to Bower's finding that strategy making in reality is constituted, to a large extent, by the resource allocation process (Bower and Gilbert, 2005).

Since 1990, 'core competence' (Prahalad and Hamel, 1990) has gained great currency among practitioners. So much so that Porter (1996) felt the need to respond with a strong reaffirmation of the importance of strategic positioning for competitive advantage. More recently, the concept of 'dynamic capabilities' (e.g., Teece, 2007) has focused strategic management researchers' attention on how an organization's resources and competencies may be combined into 'capabilities' and how these may change over time and drive the organization into new strategic directions.

It is worth noting that the positional school and the resource-based view are part of a larger set of 10 identifiable 'schools' in strategic management (Mintzberg et al., 1998), which testifies to the field's scholarly fertility but also its increasing complexity that Nag et al. (2007) tried to reduce.

An Integrative Conceptual Framework

Longitudinal field research, which examined the role of the internal ecology of strategy making in helping shape Intel Corporation's evolution (Burgelman, 2002a), provided a response to important research in organizational ecology that fundamentally questioned the role of strategic management in organizational survival and adaptation. The response was based on the view that organizations, such as Intel, are ecologies in their own right within which strategic initiatives compete for its resources, and that the role of strategic management is to orchestrate and guide this internal ecological process in light of the dynamics of the higher level, external ecological processes.

This longitudinal field research produced an integrative conceptual framework for strategic management – the 'strategy diamond' – of the dynamic forces that drive a company's evolution. This framework brings together ideas from the strategic management literature that emphasize the importance of product-market position (the industrial organization perspective) with ideas that emphasize the importance of distinctive (or core) competencies (the resource-based view), and proposes that both product-market positioning and distinctive competencies are important for the attainment of competitive advantage. In addition, the framework proposes that the reality of strategy (as opposed to the rhetoric of strategy) lies in its execution through strategic actions.

In doing so, the strategy diamond framework integrates five dynamic forces: (1) the organization's 'official (or stated) corporate strategy,' which defines the scope of the business(es) it wants to be a winner in and its intended competitive advantage relative to the other players in the industry; (2) the 'basis of competitive advantage in the industry' associated with the organization's chosen product-market position in the industry; (3) the organization's 'distinctive competencies,' which encompass the technical, commercial, and administrative and managerial competencies in which it excels to create customer value relative to competitors; (4) the organization's 'strategic actions,' which refer to the 'consequential' actions; that is, actions that commit the organization in a strategic direction and are not easily reversed (see also Ghemawat, 1991), and through which it actually uses its product-market position and distinctive competence to achieve competitive advantage; and (5) its 'internal selection environment,' which comprises the internal contextual elements that help maintain alignment of the other four forces (organization structure, planning and control systems, measurement and reward systems, recruitment and executive development, and leadership style, values, and norms). This framework serves to analyze strategic dynamics at the organization–environment interface level of analysis. Figure 1 shows the strategy diamond framework.

Figure 1 The strategy diamond: dynamic forces driving company evolution. Source: Adapted from Burgelman, R.A., March 1994. Fading memories: A process theory of strategic business exit in dynamic environments, Administrative Science Quarterly and Burgelman, R.A., 2002. Strategy is Destiny: How Strategy-Making Shapes a Company's Future, Free Press, New York.

The scalability of the strategy diamond framework, which can be scaled up and down levels of analysis (individual, functional, single business, multibusiness, or corporate), facilitates strategic integration across levels in the organization. For instance, it can be used to study the strategic situation facing the multibusiness firm as well as the strategic situation of any functional area within the firm.

The strategy diamond draws attention of strategic management scholars and practitioners to the importance of considering strategic position together with distinctive competence in order to understand and secure an organization's capacity to survive and thrive. This turns out to be surprisingly difficult. Two examples of the computer industry serve to illustrate this point. First, Novell's preeminent strategic position in network operating system market segment in the early 1980s (more than 70% market share) may have led the company to allow its distinctive competence in network operating systems to wither while pursuing nonrelated opportunities in the PC application software market segment, leading to delays in the launch of its next-generation core product and giving Microsoft an opportunity to attack Novell's core market with Windows NT. Second, Apple Computer has always had extraordinary strong distinctive competencies in software development, with many experts agreeing that the Mac operating system was superior to Microsoft's Windows operating system. Yet, because Apple's top management did not appreciate the importance of achieving a strategic position with a large installed base to gain 'increasing returns to adoption' (attracting independent software developers increases the value of the operating system, which increases the installed base and attracts even more software developers, and so on) Apple Computer was relegated to a small niche player in the PC industry.

Strategic Dynamics

Think of the connections between the basis of competitive advantage in the industry, distinctive competence, official strategy, and strategic action as 'rubber bands.' During periods of strategic alignment, the rubber bands are evenly stretched because the dynamic forces are in harmony, and the strategy diamond looks like Figure 1. Over time, however, the alignment will come under pressure as the dynamic forces become disharmonious, causing the rubber bands to stretch unevenly. The stretching of the rubber bands causes 'strategic dissonance' between the company's top and senior executives, which signals that the company likely faces an impending 'strategic inflection point' (Burgelman and Grove, 1996). Having established a baseline of alignment with the help of the strategy diamond may make it easier to understand the sources of the strategic dissonance. This, in turn, may make it easier to face up to the changes that top management must make to re-establish alignment over time in the face of changing environmental dynamics.

Role of the Internal Selection Environment

Most organizations face a tough external selection environment constituted by evolving market forces, nonmarket forces (technological change, government regulation), and general economic conditions (booms and busts). Most startup companies succumb to the pressures of the external selection environment and disappear, and even large companies or business units often face nonlinear strategic dynamics that can quickly change their relative success (Burgelman and Grove, 2007). Organizations that survive external selection gain the opportunity to substitute to some extent internal selection for external selection, which allows them to continue to outrun and outsmart the external selection environment. At the same time, however, as organizations grow and become more complex with multiple functional, product and geographic groups, and multiple levels of management, it becomes more difficult to accurately and in a timely fashion assess the pressures of a highly dynamic external selection environment.

Hence, a key set of analytical questions concerns how well the company's internal selection environment works to dynamically align strategic action with stated strategy and distinctive competence with the basis of competition in the face of changes in the external selection environment. First, to what extent do the criteria guiding the company's resource allocation – the types of projects funded and the funding levels – reflect external competitive reality? If they do not, they will probably reflect purely internal standards of performance, internal politics, or simple inertia. (General electric's determination that a business has to be #1 or #2 in its industry to remain in the corporate portfolio and Intel's rule of maximizing margin-per-wafer-start to allocate scarce manufacturing capacity to different semiconductor products are examples of criteria that reflect competitive reality.) Second, to what extent does the strategic planning process offer the opportunity to debate new opportunities? These debates typically involve those who make money today (existing opportunities) and those who promise to make money tomorrow (new opportunities), and it is rational to expect that today will usually win against tomorrow. Third, a central concern is therefore the capacity of the senior team for 'strategic recognition'; that is, how strong is the senior team's ability to see the implications of internal and external changes often *after* they are already happening but *before* others see their strategic implications? And fourth, how strong is the senior team's capacity to go from strategic recognition to strategic action; that is, their capacity for the sort of strategic leadership that forcefully drives change?

Finding valid and reliable answers to these questions may help top management diagnose the capacity of the organization's internal selection environment to maintain the key alignments over time in the face of environmental dynamics. In the case of divergences between strategy and action, for instance, this may help top management get clear about the extent to which these divergences are due to a poorly designed internal selection environment in the face of a relatively stable external selection environment, or to the fact that the internal selection environment is actually correctly picking up signals of external changes – caused either by the organization's own strategic actions to shape the external environment to its advantage or by the strategic actions of others in the external environment to which it must respond – that are putting pressure on the alignment between strategy and action.

Implications

Linking firm-level strategy and strategic action in one framework draws attention to their dynamic reciprocal relationship. For instance, as further discussed in section Strategy-Making Process, the received strategy at any given time will 'induce' (intended) action; but entrepreneurial, 'autonomous' (emergent) action may, in turn, influence the evolving strategy (Burgelman, 1983; Mintzberg, 1978). Explicitly drawing attention to both corporate strategy and strategic action also highlights the reality that the effectiveness of capabilities ultimately depends on human actors: Capabilities in and of themselves only constitute a potential. Also, the strategy diamond may help top management appreciate better that in the end strategy is only as good as strategic action, and that while strategy without capabilities is powerless, capabilities without strategy are aimless.

The strategy diamond framework also draws attention to two inertial hazards associated with potential tradeoffs between positional advantages and advantages based on distinctive competence (e.g., Barnett, 1997; Burgelman, 2002b). Such tradeoffs may create two types of strategic traps. Companies that rely heavily on positional advantages shield themselves from competitive pressures but face a potential 'position trap': The security of their positional advantage may relax their diligence in continuing to hone and develop their distinctive competencies. As a result, their existing competencies may lose some of their efficiency or strength, which may make them potentially vulnerable to new, fitter competitors attacking their strategic position. On the other hand, companies that rely heavily on distinctive competence to compete vigorously with similar others may be able to sharply hone these competencies and become best in class. However, such efforts potentially create a 'competence trap': The relentless efforts to hone existing distinctive competence may make the company vulnerable to new competitors with different distinctive competencies as competitive dynamics in the industry change (Levitt and March, 1988), or they may simply fail to appreciate the competitive importance of achieving a dominant strategic position.

Integrating the dynamic links between strategic positioning and the deployment of distinctive competence, the strategy diamond framework may potentially serve as a research tool for examining the microfoundations of dynamic capabilities, which as Teece points out can for analytical purposes "…be disaggregated into the capacity (1) to sense and shape opportunities and threats, (2) to seize opportunities, and (3) to maintain competitiveness through enhancing, combining, protecting, and, when necessary reconfiguring the business enterprise's intangible and tangible assets" (2007: 1319).

Examining dynamic capabilities in the framework of the strategy diamond may help prepare top management to better face the transient nature of all sources of competitive advantage in highly dynamic, 'hypercompetitive' environments (D'Aveni, 1994).

The strategy diamond framework also highlights the critical role of the internal selection environment in helping top management cope with such hypercompetitive external selection environments. Introducing the concept of an internal selection environment into the strategic management literature made it possible to link the field to evolutionary and ecological organization theories. It directs scholarly attention to how the internal selection environment may help a company to dynamically align strategic action with strategy and distinctive competencies with the basis of competition (given its product-market position) in the face of changes in the external selection environment and/or in response to its own strategic moves. It also provides a potential lens for studying the interplays between action and cognition in strategy-making, and may thereby become a potentially useful concept in the further development of what is now the emerging subfield of 'behavioral strategy' (e.g., Levinthal, 2011).

Finally, while it takes hard work to clearly define, and get the organization to agree upon, each of the framework's concepts in light of a specific situation, it may also help significantly speed-up the strategic recognition process because it may help top management achieve faster 'knowledge churns'; that is, the framework could serve as a theory about how to make an organization successful, a means to initiate experimental strategic actions that test that theory, and a means of interpreting the results and quickly incorporating the learning of these experimental strategic actions into the strategy going forward (through the functioning of the internal selection environment). Interestingly, the process involved in generating fast knowledge churns through the use of the strategy diamond seems to support the three capacities associated with dynamic capabilities as discussed in Teece (2007). Hence, the most important advantage of using the strategy diamond may be to help avoid the loss of precious time that moving in the wrong strategic direction inevitably entails, and which puts at least some dent in the potential competitive advantage that moving in the right strategic direction earlier offers. This also suggests that the strategy diamond framework may have the potential to serve as a research tool for helping guide the field toward a dynamic theory of strategy.

Strategizing, Economizing, and Performance

Enhancing the performance of firms in their external environment is a key factor in the definition of the strategic management field, but the link between strategic management and organizational performance, however, remains somewhat murky (Nag et al., 2007). Williamson (1994) observes that business strategy encompasses both strategizing (related to market power) and economizing (related to efficiency) and proposes that while performance can be a function of both strategizing and economizing, economizing – efficiency analysis, including governance costs as well as production costs, and comparative economic organization – is the most important factor in determining performance because all firms need economizing to survive and only relatively few firms have enough market power to do strategizing.

While Williamson emphasizes the difference between strategizing and economizing, it may be more fruitful to view these two aspects of business strategy as inherently complementary. This can be readily seen if strategizing is cast in terms of creating 'perceived value' (PV) on the part of target customers and economizing is cast in terms of 'delivered costs'

(DCs) associated with creating and delivering PV. This is shown in Figure 2 (different versions of this framework have been proposed in the literature; e.g., Porter, 1996; Saloner et al., 2001).

Figure 2 shows that at any moment in time, there exists a possibilities frontier linking DC to PV as a function of the best use of available technology (T_1) and modes of organizing (O_1). This possibilities frontier, which rules out the attainment of 'bliss' (DC-unconstrained achievement of PV), can be discovered through benchmarking to find best in class competitors at the high-end, mid-end, and low-end of the market. Most organizations will find themselves inside the frontier, and it is an important task of strategic management to try to move their organization closer to the frontier through programs such as total quality control and/or the re-engineering of business processes (see Figure 2). This requires careful analysis of the link between cost drivers and PV, and the readiness of top management to move costs from lower value-creation activities to higher value-creation activities on an ongoing basis.

Combining strategizing and economizing in a PV/DC framework also offers the opportunity to represent different types of innovation. Incremental innovation moves the possibilities frontier commensurately and makes it possible for most industry incumbent companies to adapt, sometimes taking the lead and sometimes having to catch up. Radical innovation, however, shifts the possibilities frontier in a discontinuous fashion. This involves new technological solutions (T_2 in Figure 2), for instance, the use of the Internet, new ways of organizing (O_2 in Figure 2), for instance, various forms of outsourcing, and the introduction of new business models, for instance, shifting revenue generation from selling products to providing subscription services. Such changes are often introduced by new entrants to an industry and are usually very difficult for incumbent companies to adapt to because of various forms of strategic inertia.

Strategy-Making Process

After the 1991 Napa conference, it had become clear that the strategy-making process (previously known as the policy process), also deserved systematic attention of strategic management researchers (Rumelt et al., 1994). As noted earlier, the interplay of strategy and action in the diamond model sheds light on the existence of intended/induced and emergent/autonomous strategy processes, which can be related to current work in strategic management that build on March's (1991, 2006) influential discussion of exploitation and exploration in organizational learning. Top management sets the corporate strategy and induces strategic actions by lower level leaders that are aligned with it in order to exploit opportunities in the familiar environment. The autonomous strategy process, in contrast, explores new opportunities that are outside the scope of the existing corporate strategy, relate to new environmental segments, and are often based, at least in part, on new distinctive competencies. An important top management responsibility and challenge is to balance resource allocation between the intended/induced strategy process (so as to maintain 'fit') and the emergent/autonomous strategy process (so as to maintain 'evolvability') over time; in particular, the scaling up and vectoring of resources related to autonomous initiatives that demonstrate viability through the process of 'strategic context determination' (Burgelman and Grove, 2007).

Taking into account the existence of intended/induced and emergent/autonomous strategy processes, the overall strategy-making process of a complex organization can be further characterized in terms of two key dimensions: (1) the degree of concentration (versus distribution) of strategic decision-making power, and (2) the degree to which strategy execution involves all relevant parties simultaneously (or sequentially). The combination of these two dimensions

Figure 2 Strategizing and economizing: perceived value and delivered cost. *Source: Robert A. Burgelman, Lecture Material, Stanford Business School.

Table 1 Models of strategy making

		Strategic decision-making power	
		Concentrated	*Distributed*

Reproduced from Burgelman, R.A., 2002. Strategy is Destiny: How Strategy-Making Shapes a Company's Future. Free Press, New York, pp. 4–6.

makes it possible to integrate into one conceptual framework four organizational decision-making models previously developed in the literature (Burgelman, 2002a). Table 1 shows these four strategy-making processes.

Rational actor model. A comprehensively rational top management (individual leader or leadership team) formulates the overall strategy and is able to get all the interdependent actors in the organization to simultaneously engage in the actions necessary to implement it. In this model, there is strong alignment between strategy and action. It is often viewed as the ideal type. However, it may be most effective to respond to environmental dynamics that can be reasonably well anticipated and influenced. It may also be the best model for coping with a 'clear and present danger' or for exploiting an extraordinary opportunity. While a comprehensively rational top management is in principle able to effectively balance induced and autonomous strategy processes for some period of time, they are likely to eventually start favoring the intended/induced strategy process.

Bureaucratic model. In this model, the overall strategy is still formulated by a comprehensively rational top management, but implementation is less immediate because various parts of the organization are independent of each other and translate the strategy in terms of the logic of their own operations before taking action to implement it. This model has advantages in slow-moving environments because each part of the system has time to optimize its strategic actions in light of the overall strategy. In rapidly changing environments, however, it will lead to sluggish execution of the overall strategy. While autonomous strategic initiatives will undoubtedly spring up in different parts of the system, scaling them up will be difficult. By default, the intended/induced strategy process will become dominant.

Internal ecology model. This model views organizational-level strategy as the result of successful strategic initiatives of interdependent actors (individuals or groups), who are in a position to commit the organization and who continuously try to do so. In this model, strategy making is a highly dynamic process that capitalizes on anticipated and unanticipated variations in the internal and external environments. It views the strategy making process as constituting an opportunity structure for strategic leaders in the organization, but one in which individual opportunity seeking is constrained, to some extent, by the imperative of organizational survival. This model may be most effective in highly uncertain, opportunity-rich environments. The emergent/autonomous strategy process is likely to be dominant here. Coherence of system-level strategic action depends on the characteristics of the internal selection environment.

Garbage can model. In this model, strategy making results from various independent actors taking action as a function of the sequence in which problems, solutions, and decision opportunities arise. The effectiveness of system-level strategic action depends on the sequence in which problems, solutions, and decision opportunities arise. There is neither an explicit or implicit overall strategy, nor a clear ecological survival force, serving as reference point for determining whether an initiative is induced or autonomous. Hence, by default the autonomous strategy process dominates. Arriving at a coherent overall strategy for the organization is to a large extent governed by chance. The normative implication of this model is to 'just hang in there and keep trying.'

Conclusion

Strategic management has come a long way since 1979. As Nag et al. (2007) observe, in addition to the great diversity among strategic management scholars proper, a wide variety of scholars in adjacent fields (economics, sociology, psychology, marketing, etc.) are doing significant work that has a bearing on strategic management. The launch of two new journals – *Strategic Entrepreneurship Journal* and *Global Strategy Journal* – in recent years, as well as the continued growth of the Strategic Management Society, attest to the further expansion of the field.

While this expansion is important for the continued intellectual fertility of the field and will likely lead to unanticipated, radically novel insights over time, it also poses a potential problem in terms of an ever-expanding topical universe and concomitant fragmentation of the field into specialized communities (or even camps) that have increasingly less in common. Hence, it is perhaps useful to engage in some efforts along the way to continue to integrate various important insights generated within this diverse field. That is the main purpose of the framework of dynamic forces driving company evolution (the strategy diamond), the PV/DC framework, and the framework of models of strategy making.

Strategic Planning for Public and Nonprofit Organizations

John M Bryson, University of Minnesota, Minneapolis, MN, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Strategic planning is a deliberative, disciplined approach to producing fundamental decisions and actions that shape and guide what an organization (or other entity) is, what it does, and why it does it. Strategic planning is not a substitute for strategic thinking, acting, and learning, or for leadership. Instead, strategic planning is a leadership tool meant to enhance strategic thinking, acting, and learning. Strategic planning can produce several benefits, but there is no guarantee that it will. There are a variety of approaches to strategic planning; some approaches emphasize process, while others emphasize content. Strategic management is a broader concept that links planning and implementation.

Strategic planning may be defined as 'a deliberative, disciplined approach to producing fundamental decisions and actions that shape and guide what an organization (or other entity) is, what it does, and why it does it' (Bryson, 2011: pp. 7–8). This definition implies that strategic planning is not a single thing, but is instead a set of concepts, procedures, and tools that must be carefully tailored to situations if desirable outcomes are to be achieved. Poister and Streib (1999), in a review of the field of strategic planning and management, asserted that strategic planning should:

1. Be concerned with identifying and responding to the most fundamental issues facing an organization.
2. Address the subjective question of purpose and the often competing values that influence mission and strategies.
3. Emphasize the importance of external trends and forces, as they are likely to affect the organization and its mission.
4. Attempt to be politically realistic by taking into account the concepts and preferences of internal, and especially external, stakeholders.
5. Rely heavily on the active involvement of senior-level managers, and often elected officials, assisted by staff support where needed.
6. Require the candid confrontation of critical issues by key participants in order to build commitment to plans.
7. Be action-oriented and stress the importance of developing plans for implementing strategies.
8. Focus on implementing decisions now in order to position the organization favorably for the future.

In process terms, a generic strategic planning process typically might consist of the following steps, although not necessarily in this order (Bryson, 2011):

1. Initiate and agree on the need for a strategic planning process, who should be involved and how, what key decision points will be, and a work program.
2. Clarify the various legal and other requirements that must be addressed.
3. Clarify organizational mission, vision, and values.
4. Assess the external and internal organizational environments to identify strengths, weaknesses, opportunities, and threats.
5. Identify the strategic issues, which are the fundamental policy questions or critical challenges affecting an organization's mandates, mission and values, product or service level and mix, clients, users or payers, costs, financing, organization, and/or management (Bryson, 2011: p. 55), facing the organization.
6. Formulate strategies to manage the issues.
7. Review and adopt the strategic plan or plans.
8. Perhaps establish a more refined organizational vision.
9. Develop an effective implementation process.
10. Reassess strategies and the strategic planning process.

In addition to key decision makers, there typically will be a strategic planning team, and possibly various task forces to address different strategic issues. Varied analysis, synthesis, group process, negotiation, and decision tools will be used in the different steps depending on the specific situation.

It is important to highlight what strategic planning is *not*. Strategic planning is not a substitute for strategic thinking (thinking in context about how to pursue purposes or achieve goals (Bryson, 2011: pp. 14–15)), acting (acting in context in light of future consequences to achieve purposes and/or to facilitate learning (Bryson, 2011, p. 15)), and learning (any change in a system (which could be an individual) that, by adapting it better to its environment, produces a more or less permanent change in its capacity to pursue its purposes (Bryson, 2011: p. 15). It may help people do that, but used unwisely it may hinder strategic thinking, acting, and learning. Strategic planning is not a substitute for leadership. At least some key actors must be committed to the process, or it is bound to fail. Strategic planning is also not a substitute for an organizational or community strategy. Strategies have numerous sources, both planned and unplanned. Strategic planning is likely to result in a statement of organizational or community intentions, but what is realized in practice will be some combination of what is intended with what emerges along the way. Finally, strategic planning is not synonymous with what is called 'comprehensive planning' for communities in the United States, or what has been called 'structure planning' or 'strategic spatial planning' in Europe. There may be little difference if the agency or cross-organizational group doing the comprehensive or structure planning has strong ties to government and other important decision makers. However, in practice there may be significant differences.

First, the plans are often prepared to meet legal requirements and must be formulated according to a legally prescribed process with legally prescribed content. As legal instruments, these plans have an important influence. However, the plans'

typical rigidity can conflict with the political process with which public officials must cope. Therefore, strategic plans can provide a bridge from legally required and relatively rigid policy statements to actual decisions and operations.

Second, comprehensive or structure plans are usually limited to a shorter list of topics than a government's full agenda of roles and responsibilities. For that reason, they are of less use to key decision makers than strategic planning, which can embrace all of a government's actual and potential roles before deciding why, how, where, and when to act.

Third, strategic planning on behalf of a community is typically more action oriented, more broadly participatory, more emphatic about the need to understand the community's strengths and weaknesses as well as the opportunities and threats it faces, and more attentive to intercommunity competitive behavior. Strategic planning is thus typically more comprehensive than comprehensive planning or structure planning, while at the same time producing a more limited action focus.

To summarize, strategic planning for communities comprises a set of concepts, procedures, and tools that are broader than those of more traditional urban planning. Community strategic planning is typically viewed as an important precursor of comprehensive or spatial strategic planning, since it tends to focus on the community holistically as an integrated social, economic, political, and environmental system. Strategic planning thus can help frame and articulate the broad strategies that show how land use, transportation, housing, the environment, education, economic development, health, social services, and urban branding and marketing efforts, among others, might be linked; what key points of leverage and priorities among specific strategies might be; how progress might be measured and communicated; and what lessons might be learned from ongoing implementation. United Cities and Local Governments (UCLG) (http://www.uclg.org), the largest association of local governments in the world (whose member governments cover half the world's population), calls such precursor plans City Development Strategies (CDSs). The specific form and content of CDSs vary across the globe. For example, in Latin America, many local governments have used them to address issues of inequality; in Europe, CDSs often address issues of urban competitiveness; in Asia, some cities have developed CDSs to address issues of economic development, climate change, and the need for social dialog; in North America, CDSs often address issues of financial and infrastructure crises and poverty; and in Africa and Eurasia, CDSs are being used to facilitate moves toward more decentralized planning (United Cities and Local Governments, 2010).

Strategic planning also is typically distinguished from strategic management. Strategic management, also known as performance management systems or results-based management systems are ongoing organizational designs or arrangements for strategically managing the implementation of agreed-upon strategies, assessing the performance of those strategies, and formulating new or revised strategies (Bryson, 2011: p. 323), is a far more encompassing process and is concerned with managing an organization in a strategic manner on an ongoing basis. Strategic management links strategic planning and implementation by adding ongoing attention to budgeting, performance measurement, evaluation, and management, and by adding feedback relationships among those elements (Poister et al., 2010).

Brief History of the Development and Use of Strategic Planning

Strategic planning for public nonmilitary and nonprofit purposes has its roots primarily in the business world. This history has been amply documented by others (Eden and Ackermann, 1998; Mintzberg et al., 2009). However, since around 1980, public and nonprofit use of strategic planning has skyrocketed. This experience and a growing body of literature have indicated that strategic planning approaches, when adapted to public and nonprofit organizational or community purposes, can help these entities deal effectively with their often dramatically changing environments.

In the United States – where strategic planning has proceeded the furthest – surveys indicate that strategic planning is widely used in state agencies and by local governments and jurisdictions. In addition, strategic planning is mandated for all federal departments as a result of the Government Performance and Results Act of 1993 (GPRA) and the Government Performance and Results Modernization Act of 2010. Other nations are also making increased use of strategic planning concepts, procedures, and tools for public and nonprofit organizations and communities (Bovaird and Löffler, 2009; Hughes, 2012).

Benefits of Strategic Planning

When done well, strategic planning offers a number of benefits. Advocates usually point to six main potential benefits. The first is *promotion of strategic thinking, acting, and learning*. The second is *improved decision making*, while the third is *enhanced organizational effectiveness, responsiveness, and resilience*. The fourth is *enhanced organizational legitimacy*. The fifth is *increased effectiveness of broader societal systems* to which public and nonprofit organizations contribute. Finally, strategic planning can *directly benefit the organization's people* by helping them better perform their roles, meet their responsibilities, and enhance teamwork and expertise. There is no guarantee, however, that these benefits will be achieved. For one thing, strategic planning is simply a set of concepts, procedures, and tools that must be applied wisely to specific situations. Also, even when they are applied wisely, there is no guarantee of success.

The empirical evidence on whether strategic planning actually helps is unclear. Reports published by the US Government Accountability Office (2004, 2005) indicate that while federal agency strategic planning has improved, there are still problems in establishing outcome-oriented goals, dealing with cross-agency issues, ensuring adequate consultation with external stakeholders, linking long-term and short-term goals, and identifying the financial, human, and other resources needed to implement strategies. Some also argue that the federal government's mandated top-down, fairly rigid approach limits agencies' abilities to tailor strategic planning efforts to their particular situations. However, there are numerous case study examples of successful strategic planning in public and nonprofit

organizations. In addition, surveys of public managers in the United States and United Kingdom have found that strategic planning efforts generally have helped improve organizational capacities and performance. An important feature of newer research is its emphasis on strategic planning as a *way of knowing* (Bryson et al., 2009; Balducci et al., 2011). A way of knowing means, in the first instance, a practice or customary way of doing something that allows its users jointly to develop, show, or possess knowledge or understanding. In this sense, what clearly matters is the extent to which strategic planning helps its users think, act, and learn strategically.

Approaches to Strategic Planning

Strategic planning may be divided into *process* and *content* approaches. We start by discussing broadly encompassing process approaches, then consider more narrowly conceived process approaches, and finally discuss two content approaches.

The Harvard Policy Model

The Harvard policy model was developed as part of the business policy courses that have been taught at the Harvard Business School since the 1920s (Bower et al., 1991). The approach provides the principal (although often implicit) inspiration behind the most widely cited recent models of public and nonprofit sector strategic planning. The main purpose of the Harvard model is to help an organization develop the best 'fit' between itself and its environment; that is, to develop the best strategy for the organization. One discerns the best strategy by analyzing the internal strengths and weaknesses of the company and the values of senior management, and by identifying the external threats and opportunities in the environment and the social obligations of the firm. Then one designs the appropriate organizational structure, processes, relationships, and behaviors necessary to implement the strategy, and focuses on providing the leadership necessary to implement the strategy.

Effective use of the model presumes that senior management can agree on the organization's situation and the appropriate strategic response, and has enough authority to enforce its decisions. A final important assumption of the model, common to all approaches to strategic planning, is that if the appropriate strategy is identified and implemented, the organization will be more effective. For the model to be useful for public and nonprofit purposes, it typically has to be supplemented with other approaches, such as the portfolio and strategic issues management approaches (also discussed in this section). A portfolio approach is needed because a principal strategic concern at the organizational level is oversight of a portfolio of agencies, departments, or programs. Strategic issues management is needed because much public and nonprofit work is typically quite political, and articulating and addressing issues are at the heart of political decision making.

The systematic assessment of strengths, weaknesses, opportunities, and threats – known as a SWOT analysis – is a primary strength of the Harvard model. This element of the model appears to be applicable in the public sector to organizations, functions, and communities. Another strength is its emphasis on the need to link strategy formulation and implementation in effective ways. The main weaknesses of the Harvard model are that (1) it does not draw attention to strategic issues; (2) it does not consider the full range of stakeholders; and (3) it does not offer specific advice on how to develop strategies, except to note that effective strategies will build on strengths, take advantage of opportunities, and overcome or minimize weaknesses and threats.

Strategic Planning Systems

Strategic planning is often viewed as a system whereby leaders and managers go about making, implementing, and controlling important decisions across functions and levels in the organization. When viewed this way, strategic planning is synonymous with strategic management. Strategic planning systems vary along several dimensions: the comprehensiveness of decision areas included, the formal rationality of the decision process, and the tightness of control exercised over implementation of the decisions, as well as how the strategy process itself will be tailored to the organization and managed. The strength of these systems is their attempt to coordinate the various elements of an organization's strategy across levels and functions. Their weakness is that excessive comprehensiveness, prescription, and control can drive out attention to mission, strategy, and innovation, and can exceed the ability of participants to comprehend the system and the information it produces (Mintzberg et al., 2009). In other words, the systems are prone to driving out the very strategic thinking, acting, and learning they are meant to produce.

Strategic planning systems are potentially applicable to public organizations (and, to a lesser extent, communities), for, regardless of the nature of the particular organization, it makes sense to coordinate at least some decision making across levels and functions and to concentrate on whether the organization is implementing its strategies and accomplishing its mission. However, it is important to remember that a strategic planning system characterized by substantial comprehensiveness, formal rationality in decision making, and tight control will work only in an organization that has a clear mission, clear goals and objectives, relatively simple tasks to perform, centralized authority, clear performance indicators, and information about actual performance available at reasonable cost. While some public and nonprofit organizations – such as hospitals and police and fire departments – operate under such conditions, most do not. As a result, most public and nonprofit strategic planning systems typically focus on a few issues, rely on a decision process in which politics plays a major role, and control something other than program outcomes (e.g., budget expenditures).

Stakeholder Management Approaches

Freeman (1984) states that strategy can be understood as an organization's mode of relating to or building bridges with its stakeholders. For Freeman, a stakeholder may be defined as any individual, group, or organization that is affected by, or that can affect, the future of the organization. He argues, as do others who emphasize the importance of attending to stakeholders, that a strategy will be effective only if it satisfies

the needs of multiple groups. Because it integrates economic, political, and social concerns, the stakeholder model is one of the most applicable approaches to the public sector. Many interest groups have stakes in public organizations, functions, and communities. If the model is to be used successfully, however, there must be the possibility that key decision makers can achieve reasonable agreement about who the key stakeholders are and what the response to their claims should be.

The strengths of the stakeholder model are its recognition of the many claims – both complementary and competing – placed on organizations by insiders and outsiders and its awareness of the need to satisfy at least the key stakeholders if the organization is to survive. Because of its attention to stakeholders, the approach may be particularly useful in working collaboratively with other organizations, since each party to a collaboration must be viewed as a stakeholder (Huxham and Vangen, 2005). The weaknesses of the model are the absence of criteria with which to judge competing claims and the need for more advice on developing strategies to deal with divergent stakeholder interests.

A number of other encompassing process approaches to strategic planning have been developed, primarily in the United Kingdom in the field of operations research. These include Ackermann and Eden's (2011) strategy mapping approach and Friend and Hickling's (2005) strategic choice approach. They are now beginning to be used more widely around the world.

Strategic Issues Management Approaches

These approaches are process components, pieces of a larger strategic planning process. The concept of strategic issues first emerged when practitioners of corporate strategic planning realized that a step was missing between the SWOT analysis of the Harvard model and the development of strategies. That step was the identification of strategic issues, or crucial challenges facing the organization. Many organizations now include a strategic issue identification step as part of full-blown strategy revision exercises, and also as part of less comprehensive annual strategic reviews between major strategy revisions. In addition, many organizations have developed strategic issue management processes actually separated from annual strategic planning processes. Many important issues emerge too quickly to be handled as part of an annual process.

Strategic issue management is clearly applicable to public organizations, since the agendas of these organizations consist of issues that should be managed strategically (Ackermann and Eden, 2011). The strength of the approach is its ability to recognize and analyze key issues quickly. The approach also applies to functions or communities, as long as some group, organization, or coalition is able to engage in the process and manage the issue. The main weakness is that, in general, the approach offers no specific advice on exactly how to frame the issues other than to precede their identification with a situational analysis of some sort. Nutt and Backoff (1995) have gone the furthest in remedying this defect.

The final four process approaches to be discussed are *process strategies*. Two are primarily organizational: logical incrementalism and strategic planning as a framework for innovation. Two are primarily multiorganizational: contract approaches and collaboration. Process strategies are approaches to implementing a strategy that typically has already been developed in very broad outline and is subject to revision based on experience with its implementation. Other important process approaches not discussed in this article, due to space limitations, include total quality management (Cohen and Eimicke, 1998), the mutual gains approach (Susskind and Field, 2010), and the management of culture (Schein, 2010).

Logical Incrementalism

In incremental approaches, strategy is a loosely linked group of decisions that are handled incrementally. Decisions are handled individually below the organizational level because such decentralization is politically expedient – organizational leaders should reserve their political clout for crucial decisions. Decentralization also is necessary since often only those closest to decisions have enough information to make good ones. The incremental approach is identified principally with Quinn (1980), although the influence of Lindblom (1959) is apparent. Quinn developed the concept of *logical incrementalism* – or incrementalism in the service of overall organizational purposes – and, as a result, transformed incrementalism into a strategic approach. Logical incrementalism is a process approach that, in effect, fuses strategy formulation and implementation. The strengths of the approach are its ability to handle complexity and change, its emphasis on minor as well as major decisions, its attention to informal as well as formal processes, and its political realism. A related strength is that incremental changes in degree can add up over time into changes in kind. The major weakness of the approach is that it does not guarantee that the various loosely linked decisions will add up to fulfillment of organizational purposes.

Logical incrementalism would appear to be very applicable to public and nonprofit organizations, as long as it is possible to establish some overarching set of strategic objectives to be served by the approach. When applied at the community level, there is a close relationship between logical incrementalism and collaboration. Indeed, collaborative purposes and arrangements typically emerge in an incremental fashion as organizations individually and collectively explore their self-interests and possible collaborative advantages, establish collaborative relationships, and manage changes incrementally within a collaborative framework (Huxham and Vangen, 2005; Innes and Booher, 2010).

Strategic Planning as a Framework for Innovation

As noted in the 'Strategic Planning Systems' section, strategic planning systems can drive out attention to mission, strategy, and innovation. The systems, in other words, can become ends in themselves and drive out creativity, innovation, and new ventures without which the organization might become irrelevant or die. Many organizations, therefore, have found it necessary to emphasize innovative strategies as a counterbalance to the excessive control orientation of many strategic planning systems (Osborne and Brown, 2012). The framework-for-innovation approach relies on many elements of the approaches discussed in this article, such as SWOT analyses and portfolio methods. This approach differs from earlier ones in four emphases: (1) innovation as a strategy; (2) specific management practices to

support innovation; (3) the development of a mission or 'vision of success,' which provides the decentralized and entrepreneurial parts of the organization with a common set of superordinate goals toward which to work; and (4) the nurturing of an entrepreneurial organizational culture.

The main strength of the approach is that it allows for innovation and entrepreneurship while maintaining central control of direction. The weaknesses of the approach are that typically – and perhaps necessarily – a great many, often costly, mistakes are made as part of the innovation process and that there is a certain loss of accountability in very decentralized systems. Those weaknesses reduce its applicability to the public sector, in particular, in which mistakes are less acceptable and the pressures to be accountable for details (as opposed to results) are often greater. Many nonprofit organizations will also have trouble pursuing this approach because a shortage of important resources will magnify the risks of failure.

Contract Approach

The contract approach is another popular system of institutionalizing strategic planning and management, especially in simple to moderately complex shared-power environments. The contract model is employed for much of the planning and delivery of many publicly financed social services in the United States via either public or nonprofit service providers (Milward and Provan, 2003). The system is also used to institutionalize strategic planning and management in school districts with site-based management.

In this system, there is a *center* that establishes strategic objectives for the jurisdiction or organization as a whole, negotiates contracts with individual units of management, monitors performance, and ensures the integrity of the system. In the language of economics and *principal–agent models*, the center is the *principal* and the individual units of management are the *agents*. The contract between the center and a unit outlines the unit's expected performance, defines its resources, lists other support the unit can expect from the center, and describes a review and renegotiation sequence. Within the framework and legal strictures of the contract, general managers of individual units and their staffs are free to do whatever they think is necessary or desirable to ensure adequate performance. At its best, this approach allows both the center and the individual units to focus on what is important for them – both are empowered to do their jobs better. In such a system, there would be a strategic plan for the center and one for each of the units. Key system concerns would include the content and approach embodied in the center's plan, the center's difficulties in acquiring adequate information, the proper alignment of incentives for the principal and the agents, the difficulties that the center may have in exercising control in the face of a large number of contractors, and ways to ensure adequate investments by the units if they cannot be sure of a long-term contract.

Collaboration Approach

Collaboration represents the final process approach to be discussed. Like contracting, collaboration is increasingly being used to govern and manage in shared-power environments. In fact, the contract system represents a classic form of collaboration, but there are many different (and often more complicated) approaches to collaboration that are more suitable than competitive contracting for situations involving moderate to high levels of complexity and ambiguity (Agranoff, 2007). Human service systems often embody contracting and additional collaboration approaches – contracts for what can be specified and governed with reasonable ease, and supplemental collaboration for those situations involving higher levels of complexity and ambiguity, and therefore requiring greater reliance on trust, shared norms, professionalism, and learning-by-doing for effective governance and management (Huxham and Vangen, 2005). In the latter case, collaboration overlaps with strategic issue management and stakeholder management approaches.

Collaboration is particularly useful when addressing problems for which no organization is fully in charge. Situations of this sort occur when, for example, there is a marked degree of separation between the source and use of funds, services are jointly produced (that is, service recipients are at least partly responsible for effective production, as in mental health services), or the key governance and management task is arranging networks rather than managing hierarchies (Milward and Provan, 2003).

Collaboration involves varying degrees of sharing power and resources (such as information, money, clients, and authority) between units to achieve common ends that could not be achieved separately. There are three different archetypal approaches to collaborative network management (Provan and Kenis, 2007): *lead organization*, *shared governance*, and *partnership administrative organization*.

In the *lead organization* approach, a single partner organization coordinates the major collaboration activities and key decisions. The lead organization has more power than the other partners, who typically are moderate in number. Milward and Provan (2003), in their longitudinal study of mental health service delivery networks, have found that network effectiveness is greatest when there is a strong central integrating unit; clear and consistent lines of authority and accountability embodied in contracts; aligned incentives that give everyone a stake in the success of the network; system stability; and munificent resources. These factors allow constructive norms, social capital, and network learning capabilities to develop, and needed incremental investments and changes to be made.

A key system concern with the lead organization approach is how to achieve the right balance between network stability and adaptability. Because of the importance of stability to performance, a system probably should be changed infrequently and, if possible, incrementally. Another key concern will be the continual need to make sure that incentives are aligned properly so that participants have an incentive to maintain the network and high performance levels.

The *shared governance* approach is likely when no partner has significantly greater power and resources than the others and no external governance organization is formed or mandated. The viability of the approach depends on each organization's involvement and commitment, as the partners are responsible for managing internal and external relations (Provan and Kenis, 2007). Viability also depends on reasonable goal consensus, since exit is always an option for member organizations. If the number of organizations participating in shared governance becomes too large, and if trust levels decline, goal consensus

becomes a bit shaky, and the collaborators have limited collaboration abilities, the partners may create a separate administrative entity – a *partnership administrative organization* (PAO) – to govern the collaboration and its activities and decisions. The PAO is a separate organization whose purpose is to manage the collaboration. A strength of the PAO approach is that presumably the capacity exists to manage the network. A weakness is that the PAO may become disconnected from the concerns of the organizations in the network.

In sum, 'process' approaches do not prescribe answers, although good answers are presumed to emerge from appropriate application. In contrast, 'content' approaches do yield answers. In fact, the models are antithetical to process when process concerns get in the way of developing the 'right' answers. In the 'Portfolio Models' and 'Competitive Analysis' subsections, we discuss two content approaches: portfolio models and competitive analysis. Other important primarily content approaches not covered in this article, due to space limitations, include reengineering and systems analysis.

Portfolio Models

The idea of strategic planning as managing a portfolio of 'businesses' is based on an analogy with investment practice in which an investor manages a portfolio of stocks to balance risk and return. Although the applications of portfolio theory to the public sector may be less obvious than those of the other approaches described in this section, they are nonetheless just as powerful (Bryson, 2011). Many public and nonprofit organizations consist of 'multiple businesses' that are only marginally related. Often, resources from various sources are committed to these unrelated businesses. That means that public and nonprofit managers must make complex portfolio decisions, although usually without the help of portfolio models that frame those decisions strategically.

The strength of portfolio approaches is that they provide a method of measuring entities of some sort (e.g., programs, proposals, or problems) against dimensions that are deemed to be of strategic importance (usually the attractiveness of the option versus the capability to implement it). Weaknesses include the difficulty of knowing what the appropriate strategic dimensions are, the difficulties of classifying entities against dimensions, and the lack of clarity about how to use the tool as part of a larger strategic planning process.

Portfolio approaches can be used in conjunction with an overall strategic planning process to provide useful information on an organization, function, or community in relation to its environment. However, unlike the process models, portfolio approaches provide an 'answer'; that is, once the dimensions for comparison and the entities to be compared are specified, the portfolio models prescribe how the organization or community should relate to its environment. Such models will work only if a dominant coalition is convinced that the answers they produce are correct and the coalition is willing to act based on the answers.

Competitive Analysis

Another important content approach that assists strategy selection has been developed by Michael Porter (1998a) and his associates and adapted to public purposes by Vining (2011). Porter (1998a) hypothesizes that five key competitive forces shape an industry: the relative power of customers, relative power of suppliers, threat of substitute products, threat of new entrants, and amount of rivalry activity among the players in the industry. The assumption is that the stronger the forces, the greater the profitability potential for businesses and industries. For many public and nonprofit organizations, there are equivalents to the forces that affect private industry. An effective organization in the public and nonprofit sector, therefore, must understand the forces at work in its 'industry' in order to compete effectively, and must offer value to its customers that exceeds the cost of producing it. On another level, planning for a specific public function (health care, transportation, or recreation) can benefit from competitive analysis if the function can be considered an industry. Vining (2011) has adapted the five-forces model specifically for a public agency. He hypothesizes that the relevant five competitive forces are the relative power of agency sponsors and customers (a modification), the relative power of suppliers, the threat of substitute products and new entrants (combining two of Porter's forces), political influence (a new force), and the intensity of rivalry among agencies. Vining posits that the stronger the forces, the less the agency's autonomy and the poorer its performance, because it will have little room or incentive to make improvements. Similarly, the weaker the forces, the greater the public agency's autonomy and, up to a point, the better the agency's performance. Too much autonomy is presumed to be bad for performance.

In addition, Porter (1998b) points out that for the foreseeable future, self-reinforcing agglomerations of firms and networks are crucial aspects of successful international economic competition. In effect, not just firms and nations but also metropolitan regions (Shanghai, the Silicon Valley, New York, London, and Paris) are key economic actors. Regions interested in competing on the world stage should therefore try to develop the infrastructure necessary for virtuous (rather than vicious) cycles of economic growth to unfold. In other words, wise investments in education, transportation and transit systems, water and sewer systems, parks and recreation, housing, and so on can help firms reduce their costs – particularly the costs of acquiring an educated labor force – and thus improve the firms' ability to compete internationally.

The strength of competitive analysis as proposed by Porter is that public and nonprofit organizations can use competitive analysis to discover ways to help the private firms in their regions. When applied directly to public and nonprofit organizations, however, competitive analysis has two weaknesses: it is often difficult to know what the 'industry' is and what forces affect it, and the keys to organizational success in the public and nonprofit world are often success in accommodating political forces and using collaboration instead of competition. Competitive analysis for public and nonprofit organizations, therefore, must be suitably adapted and coupled with a consideration of social and political forces and the possibilities for collaboration (Vining, 2011; Huxham and Vangen, 2005).

Conclusions

It should be noted that careful studies of corporate-style strategic planning in the public and nonprofit sectors are few in number, but the evidence on balance indicates that strategic planning in general appears to be helpful (Poister et al., 2010; Andrews et al., 2012). Beyond that, it is possible to reach some tentative conclusions. First, it should be clear that strategic planning is not a single concept, procedure, or tool. In fact, it embraces a range of approaches that vary in their applicability to the public and nonprofit sectors and in the conditions that govern their successful use. Second, while any generic strategic planning process may be a useful guide to strategic thinking, acting, and learning, it will have to be applied with care in a given situation, as is true of any planning process. Because every planning process should be tailored to fit specific situations, every process in practice will be a hybrid. Third, public and nonprofit strategic planning is well on its way to becoming part of the standard repertoire of public and nonprofit leaders, managers, and planners. Because of the often dramatic changes these people and their organizations confront, we can hypothesize that the most effective leaders, managers, and planners at the beginning of the twenty-first century are, and will be increasingly in the future, the ones who are best at 'strategic' planning. Finally, research must explore a number of theoretical and empirical issues in order to advance the knowledge and practice of public sector strategic planning. In particular, strategic planning approaches that are responsive to different situations must be developed and tested. These approaches should specify key situational factors governing their use; provide specific advice on how to formulate and implement strategies in different situations; be explicitly political; indicate how to deal with plural, ambiguous, or conflicting goals or objectives; link content and process; indicate how collaboration as well as competition are to be handled; and specify roles for those involved in the process. Other topics in need of attention include the nature of strategic leadership; ways to promote and institutionalize strategic planning across organizational levels, functions that bridge organizational boundaries, and intra and interorganizational networks; the ways in which information technologies can help or hinder the process; and how best to engage the public in strategic planning. Progress has been made on all of these fronts, but work is clearly necessary if we are to understand better when and how to use strategic planning.

This article is a revision of the previous edition article by J.M. Bryson, volume 22, pp. 15145–15151, © 2001, Elsevier Ltd.

Abstract

The business strategy field covers business practice and academic research but the two are not strongly related. A history of the topic is presented and the two views are contrasted. One is the academic discipline's view that strategy is the rigorous pursuit of optimal performance. The other, a practitioner's view, sees strategizing as addressing the 'What do we do now?' question, always present for strategists to inhabit uncertain situations. We follow Knight's intuition that profit only arises as strategists engage real world uncertainties through their firm's practice.

The Strategy Field's History

As strategy textbook authors are quick to point out, strategizing is an ancient topic. The beginnings of todays' theorizing came with Chandler's analysis of the relationship between 'strategy' as the firm's chosen market engagements and 'structure' as its chosen administrative means (Chandler, 1962). He sought an efficient 'fit' between environment and firm, between strategy and structure, a view so taken for granted that it is difficult to find any other definition. The external–internal fit (EIF) paradigm dominates the strategy textbooks – as in the external assessment of threats and opportunities and the internal assessment of strengths and weaknesses (SWOT). EIF was jolted by Porter's 'competitive strategy' analysis (Porter, 1980). His thinking derived from industrial organization economics and paid little attention to efficiency. It focused on protecting the firm's rent streams (above average returns) from those economic actors able to disturb or appropriate them. Though interfirm rivalry is considered, Porter's is not an industry analysis, as many assume, for many of the players in his familiar 5-box model are actually outside the focal firm's industry (Spender and Kraaijenbrink, 2011). The underlying presence of market power ('force' in Porter's terminology) showed that firms are not the passive adapters implied in the EIF analysis but can push back aggressively against those eroding their rent streams or threatening to – with repricing, R&D, new products, negotiating, and signaling. Porter summarized his competitive approach by contrasting (1) differentiation, the rent-protection paradigm, and (2) cost leadership, restating the EIF paradigm – though he noted later that his 'generic strategies' analysis was an 'afterthought.' The shift from efficiency to rents was also in tune with changing politics, as the Reagan and Thatcher administrations rolled antitrust regulations back to give monopolists freer rein.

By the end of the 1980s, strategy researchers were looking for ways to explain how firms might acquire and protect their rent streams in dynamic competitive situations (Rumelt et al., 1991). One conjecture was that a firm's rents would derive only from its ownership of those valuable, rare, and inimitable (VRIN) resources that could be integrated into the firm's operations – the resource-based view (RBV). Missing, though, was any explanation of how firms might (1) acquire VRIN resources without their rent potential being stripped in the factor markets or (2) transform these resources into added economic value. Answering either question would escape the tautology that valuable resources beget value. Wildly popular among strategy academics, in spite of being little supported by empirical research or having clear managerial implications, the RBV provoked a second conjecture, sometimes dubbed the knowledge-based view (KBV) (Kraaijenbrink et al., 2010). The intuition was that the firm's 'learning' can produce new rent-yielding VRIN resources internally, where they will be shielded from market forces and be inimitable. Theorists borrowed earlier notions of firms as 'bundles of resources, competences, and capabilities.' There was attention to the dynamics of learning with notions like 'dynamic capabilities' (DCs), resources that would enable firms to generate new rents when changing circumstances eroded their existing rent streams. But missing, as with the RBV, was an appropriate 'theory of the firm' as comprising resources, competences, or capabilities – dynamic or otherwise.

The strategy discourse was again reshaped or 'colonized' by new connections with post-WWII microeconomics, especially with responses to Coase's questions about the 'nature of the firm': "Why do firms exist, why are their boundaries where they are, why are their internal arrangements as they are, and why is their performance so varied?" (Coase, 1937). Researchers began to incorporate transaction cost analysis, principal-agent theory, information asymmetry, moral hazards, contracts, and allocation of property rights. There was empirical research into vertical and horizontal integration, interfirm alliances, mergers and acquisitions, initial public offerings (IPOs), networks, and alternative modes of financing and governance. Countering the microeconomic impulse was renewed attention to the EIF paradigm and strategizing as planning for the long term. This focused on the intraorganizational processes of strategic plan formulation (strategy process, strategy-as-practice, case analysis), their behavioral and psychological aspects (top management teams, HR strategy, incentive and pay schemes, organizational communication, knowledge management, and behavioral strategy), and on improved environmental analysis (business intelligence, data mining, scenario planning, and risk analysis). In the background a single metaphor – the strategist viewing the firm's situation objectively, gathering information, and processing into a rigorous actionable conclusion. It dominates strategy research and helps

explain why journals are packed with quantitative data that probes for causal relationships between outcomes, as dependent variables, and situational information as independent variables. There are plenty of reasons to doubt this metaphor's practical usefulness, for Simon's notion of 'bounded rationality' looms. No business people – or academics – are 'perfectly rational.' But still our discipline's textbooks and articles are written as if conclusive data are available, meaningful, and computable. Theory is the thing in question, the data to be computed is not – and thus practice does not appear.

But the essence of strategizing is the practical difficulty of choosing action in the face of a real situation's uncertainties. Strategizing deals with the challenges of acting 'mindfully' in one-off uncertain situations, unique or, more specifically, situations open to being made unique by the strategist's choices. Strategizing is how human beings pursuing their goals identify what is specific to their situation, the features that are material to action that cannot be generalized, and so neither covered by theory, nor ignored. There is a connection to Polanyi's notion of tacit knowing; strategy points directly to the tacit dimensions of human action rather than to its explicit rational dimensions. The strategist's judgment particularizes the firm's situation. Given the pervasiveness of uncertainty, it is difficult to understand why our discipline has devoted so much effort to analyzing situations that deny it and make the analysis irrelevant to practitioners.

Engaging the Unique

Strategic practitioners exercise their judgment under uncertainty in ways that are subjective and personal. In practice, the strategist's world is uncertain in three ways – their own ignorance, or the situation's indeterminacy, or the incommensurability of differing aspects of what the strategist's knows (Spender, 2007). The strategist must construct a view within which to think. This takes five steps: constraint discovery, constraint identification, judgment, creating a language for persuading others' judgment, and implementing practice – which includes managing the learning from the implementation experience. First, step 1, the strategist must discover the degree or manner in which the situation (knowledge-absence chosen) is underdetermined and open to her/his judgments yet constrained in ways beyond her/his power to change. This identifies the strategist's 'option space.' The positivist way of thinking is that independent variables must fully determine the strategist's decision. But while real-world choice is always constrained by some 'facts' because of uncertainty it is never constrained to the point of being fully determined. As actors in an uncertain world we are always strategists and always have choices, even under the most constraining circumstances. It follows that the facts to be taken into account must be selected, and they are never self-evident and beyond doubt. What must be attended to? Simon argued that managerial attention was the organizational resource in shortest supply, so the essence of strategic choice lies in knowing what to pay attention to, on the grounds that much is relevant but not everything.

The private sector business strategist has little choice over government regulations affecting the firm's goods and services, patents, and other forms of valuable knowledge to which the firm has no access, labor contracts made on an industry-wide basis, constraints to the supply of the relevant factors of production, many costs, such as transportation costs and taxes, and so on. This leads to our realizing that each firm or, rather, its business model, is unique. One question is "How many constraints need to be taken into account?" for the list threatens to be endless, almost anything might matter. The strength of strategic consulting tools is their confidence that the strategist's problem can be boiled down to a few essentials: strengths, weaknesses, opportunities, and threats (SWOT) or cash cows, question marks, and stars Boston Consulting Group (BCG) or, in the case of the balanced scorecard – matters financial, marketing, internal, and growth. Empirical research by the present author suggested most business models address around a dozen strategic issues (Spender, 1989).

With an inventory of constraints in place, the strategic opportunity space is not finally framed until the practical nature of each constraint has been explored. This is step 2, exploring whether the specific constraint is a matter of ignorance, of indeterminacy, or of incommensurability. In practice the constraints to a firm's strategic maneuvering are seldom known as brute facts, but are always open to interpretation and manipulation. Constraints of ignorance can be shifted advantageously by research. Perhaps R&D has an impact, or 'data mining,' or 'industrial espionage.' The firm's activity is here directed toward what is in principle knowable. But sometimes other actors, such as competitors or regulators, put a different type of constraint in place, not knowable until enacted. But they can also be moved to strategic advantage by exercising power, perhaps negotiating directly or indirectly with the others, or lobbying, signaling, or bribery. Finally the constraint in question might be incommensurability "How do these facts or relationships fit together?" The strategist's capacity here might be labeled an intellectual or imaginative power. Overall the strategist always has a degree of power to act on or refashion the strategic opportunity space, to address it proactively rather than remain passive.

Step 3 is the practical act of strategic judgment, and this cannot be theorized, of course, no more than it is possible to theorize why Picasso painted in one way rather than another – even after the constraints of the materials, subject, and timing are appreciated. Nonetheless some useful things can be said about acts of judgment. Von Clausewitz wrote of personal preparation for military strategizing, deep study of military history and biography, study of facts such as the terrain and the military resources available, but also of the need to clear the mind so that strategic insights can arrive; perhaps sleep on a major decision or take a walk to clear the head, and so on (Sumida, 2008). Von Clausewitz was especially interested in strategizing as choosing the place, time, and manner of engagement. Timing may be everything.

With step 3, the business model comes together and the language created becomes the means to justify the choice of constraints and how they are interpreted. It is an innovation bringing something new into the world as a result of the practice it precipitates. Any action in an uncertain world is an innovation, of course, but the most profound and advantage-yielding innovation a strategist can generate is a new business model, a new way of adding economic value in the world. Its novelty may be modest, a new way of dealing with the same set

of constraints (incremental), or more innovative, provoking an entirely new way of dealing with them (radical). But the most significant innovations arise from changing or repositioning constraints, especially those impacting others' business models (game changing).

With the new business model in place, step 4 follows and leads toward strategic practice. The ultimate test of strategizing is 'Does it work?' The relationship between analysis and practice hinges on the possibility of an analysis that tests the business model's viability ahead of implementing it, irreversibly committing resources. So long as bounded rationality is taken seriously there can be no possibility of taking everything into account, no preparation can secure the actors from surprise. The doing is always different from the thinking about it. There comes that crucial point when the actor must 'jump in with both feet' and expose her/himself to the unconsidered. In business situations the rawness of this act can be shared because most activity is collaborative. Others can help. So the essence of step 4 is strategic conversation with those others whose judgment might bear usefully on the situation, increasing the strategist's confidence without, of course, ever entirely eliminating the risk (Spender and Strong, 2014). The strategist always remains responsible.

Engaging Others

With steps 1, 2, 3 completed and step 4 in hand, the strategizing process focuses on the creation of the firm. The bridge between entrepreneurial/strategic ideas and the real world is crossed by practice. Instead of viewing the firm as a taken for granted command and control machine to be directed this way or that, the firm must be considered problematic, something to be constructed by the strategizing process. It is a dynamic and tentative bundle of collaborative practice – never tidy, with elements of error and surprise intermingling. Value is only created by practice, instantiation. Planning and thinking are fine, but the firm's purpose is the added value that arises through its practices and their specificities. The result is the firm and as close as one can get to its bundle of activities, a situationally specific language that embraces, shapes, and justifies the practices of those involved. As a result the business is a discursive life space, its actors inhabit as they apply their skills and generate value. But, who gets told what is in this language?

The difference between analysis and synthesis has a huge impact on communications within the firm and the network of those who can respond to the strategist's choosing. There are the external agents indicated in stakeholder theory: moneymen, customer action groups, and focus groups. There are the R&D people. There are the employees, especially valuable sources of judgment when adding value calls for skills in the transformation of inputs into outputs or dealing with customers' wishes. There are the lead users, open innovators, and market makers. All may have important judgments to contribute to the enterprise. The wise strategist resists the temptation that comes with responsibility, to cut herself or himself off and hide out in isolation. Judgment is necessary to manage the delicate balance between being present as a leader, remaining in charge and responsible, or as a listener, open to others' opinions, being aware of what is going on in and around the situation being strategized. The judgments to be made about who and what to listen to are complementary to the process of promulgating the strategic choices arrived at (Spender and Strong, 2014). Who should be heard and who told? Organizational communications, especially about strategy, matter greatly and interact with the patterns of power and authority that are essential to the firm's smooth functioning.

The difference between analysis and synthesis illuminates communication. Given the strategist's primary function is to lead the firm toward engaging uncertainties in ways that result in added value, strategic communication has little to do with broadcasting conclusions or giving directions. The uncertainties chosen must be grasped and resolved if the firm is to hold together, function, and prosper. When the leader absorbs all the uncertainty those acting in the situation are aware of, the result may not be entirely beneficial. The leader's principal contribution is to shape workplace activity – which includes the firm's network of external arrangements and distribution and purchasing channels – so that the remaining uncertainties can be engaged and resolved by those doing the work. No matter how thorough the leader's strategizing, there will be uncertainties remaining that can only be resolved as the work is being done. But the worker's judgment and synthesizing capabilities must be applied in ways that reflect the strategist's choice of objective. On the one hand the experience of working is enriched when there are uncertainties to be resolved and judgments to be made in addition to completing the task. For many this marks the difference between empowering work and mindless labor. But if too much of the uncertainty remains unresolved or too little support is provided, the work situation becomes overly stressful, discouraging, and maybe undoable. On the other hand if too little uncertainty remains this may dull the subordinates' work. They find little that engages their creative capabilities, whose exercise binds them into the activity.

By making uncertainty central, strategizing goes way beyond developing a plan of action to address a chosen objective. It becomes a matter of building a human apparatus with which the strategist grasps and engages selected knowledge-absences that are only resolved through creative practice, and so yield an added value. It is the vital core of the firm as the most important apparatus invented to advance the human condition. Highly specific language is its key as a managed domain of interpersonal practices. The business model – as the firm's specific language – builds the firm by communicating with those whose judgment and activities bring it to life (Spender, 2014). Direction and instruction can be contrasted against encouraging proactive creative engagement. Direction and instruction, especially when both necessary and sufficient to completing the task, positions the worker as the strategist's passive instrument, channeling the strategist's thinking – vs the different relationship implied when the strategist passes specific uncertainties to others to resolve, seeking their judgment in their resolution, to deal with uncertainties the strategist was not able to resolve. The one presumes a submissive authority relation, the other presumes respectful creative collaboration; and nontrivial strategizing demands the second because the strategist cannot arrive at a full and final resolution of all the uncertainties arising from the knowledge-absences chosen. How is a collaboration of diverse judgment achieved?

Much of the literature on organizational communication presumes the firm is like an electrical network with instruction signals passed without loss through the administrative apparatus to individual work roles that are thereby fully controlled – while accountability and performance signals flow back to the strategic nerve center. The firm is envisaged as the rigorous solution to a communication system design problem. Strategy has little relationship to this metaphor. The distinction made earlier between strategically trivial decision making in circumstances in which full data are available and the nontrivial situations in which uncertainties are engaged, is paralleled by the distinction between instruction and the human communication that results in creative engagement. If the strategic task is nontrivial, it follows the firm is more than a design problem. Rather, strategizing works by capturing the vitality of the firm's participants, and thereby the firm gains the capacity to absorb and resolve uncertainty, and make profit. The firm is a group of creative people unified by a firm-specific language. They collaborate, applying their judgment to engage chosen uncertainties far beyond those that can be handled by the individuals alone – a movie production, perhaps, or an expedition to the Moon, or a modern hospital. The key to managing the distribution of uncertainties is not to pass them to others to deal with as they wish. To the contrary, the others' judgment has to be harnessed and channeled toward objectives the strategist has chosen.

It is useful to contrast mechanical or electrical communication – such as that which takes place between computers – with the broad range of human communications considered within the study of rhetoric. Machine communication depends on the presence or absence of a signal, of data. The meaning of the data is not at issue. Because of our bounded rationality and doubts about facts, human communication always concerns both data and meaning (Spender, 2007). Meanings are what we attach to data and managing them is as much of a challenge as is getting data. Human communication is generally less about data than about meaning. Paying attention to the distinction between data and meaning separates the strategic task into two complementary spheres. On the one hand there are steps 1, 2, and 3 – discovery, applying judgment and getting to grips with an uncertain situation, and selecting and creating the business model's facts and meanings. On the other, step 4, the process of drawing other peoples' judging capacity into the firm by managing the meanings they attach to the data considered in their work.

Rhetoric shows how meanings are managed, for they cannot be communicated as data. Ultimately meanings are what we create and add in order to make sense of the data we receive. As Aristotle told us, human communication has three parts or 'modes' that are incommensurate – *logos*, *ethos*, and *pathos*, the different types of communication that reflect the different ways in which human beings know, understand, and debate meaning. *Logos* concerns communication that appeals to an audience's rationality and objectivity and is the mode of communicating that works well with data, when meanings are not problematic and can be taken for granted – time of day, number of points in a basketball game. *Ethos* concerns an appeal to the social relationship between audience and rhetor (leader/strategist) and draws people toward letting their meanings change. When an admired person speaks, we listen; we may be persuaded to think in a new way because we respect the speaker. *Pathos* appeals to the audience's emotions. Emotion is the driver to human action; persuasion alone is insufficient. Getting people to agree is not the same as getting them to act as you wish. Rhetoric tells us that effective communication toward chosen actions synthesizes all three modes into a situated discourse.

Strategizing arcs from the realm of thinking into purposive practice but cannot ever be separated from its action dimensions. There can be no abstract or rigorous theory of strategizing. The language that the leader/strategist needs to harness the judgment of others toward the firm's chosen goals in step 4, and thereby transform the chosen strategy into the added value sought, stands on the empirical constraints explored in steps 1, 2, and 3. The language developed persuades the other actors to support the strategist by pointing out (1) what to pay attention to, and (2) how to interpret and act on what they discover. There is an additional wrinkle here in that human communication is far from being bounded by data and meaning – taken together to comprise 'information.' Strategizing reaches beyond this, and the various forms of nonverbal signaling and into the firm's tacit knowledge resources. The strategist seeks to harness the others' skills, often tacit, as well as their explicit information resources, for their support is crucial to implementing the strategy successfully. Rhetoric's focus on practice reaches beyond merely shaping how people think and delves into engaging others to act resourcefully, imaginatively, and purposively in the specific context of their action.

At the same time, since these supportive and skillful others are being drawn into contributing imaginatively by being immersed in the value adding practices – the antithesis of participating dumbly – so they become aware of the nature of the uncertainties being engaged and of subtlety of their relationship with 'the leadership.' Whose judgment rules? Given uncertainty, the balance is constantly open to question. But what questions? Rhetoric can help clarify here, for one branch of rhetoric covers 'question theory.' Most know of rhetoric as the process of persuasion, a speaker engages the audience and moves them to act. Those in the audience are thereby transformed into people they were not previously – they get 'with the program.' They are immersed in a new way of living and, because that is also under uncertainty, a new set of existential questions arises for each of them. So everyone involved and committed to the firm looks to the strategist/s to reassure them that the firm (1) has a viable business model that adds value, (2) has a means of estimating its viability ahead of implementing it, (3) appreciates the principal threats to this viability, (4) has a sense of how to change the firm's business model as needed, and (5) has a sense of how long it will remain viable.

This places the business model between the strategist's identity, intentions, and context in two different ways. First, it encapsulates the firm's identity and intentions as sources of the judgments articulated into its strategy. These shape how those involved view the firm and its context. But the way the actors view their experience of these is likewise shaped for all learning is mediated and conditioned by what is known already. The business model is both a bridge out from thinking to practice, and a bridge back from practice to better thinking. Thus, step 5 of the strategizing process does not stop with measuring the firm's performance against its strategic intentions. It embraces managing what those involved have learned from the practices

that resulted from the previous steps. Step 5 completes the cycle of strategizing and finalizes the business model as a dynamic pattern of managed responses in an ongoing and incompletely predictable context.

Conclusion

Business strategy is a field of research and of managerial practice. The last few decades of academic research have produced a big literature but business practice has not been much informed; though there are important exceptions in highly specialized areas that bring high-speed and large-scale computing and data analytics to business decision making. Beyond these it seems clear that researchers and practitioners have moved in separate directions. Academic research has flourished nonetheless; to the point the field now comprises a large variety of mutually inconsistent ways of looking at its central problematic – the generation of theory that explains firm performance and competitive advantage. Attempts to rein in this proliferation have failed and show no prospect of succeeding.

Instead of hoping for a long-sought overarching theory of business strategy that would underpin rigorous research and show businesses how best to meet their goals and gain competitive advantage, there is a different way of proceeding. It follows from Knight's distinction between circumstances that are (1) knowable vs (2) situations of irrevocable uncertainty (Knight, 1921). Instead of presuming, as do most theorists today, that an economy is fully knowable, Knight adopted a humbler position, that man's understanding of reality is always limited – and economies that are real call for strategizing. Knight's approach was not new, obviously; but he went further and presumed the possibility of economic profit and added value lay in imaginative (entrepreneurial) engagement with real-world uncertainties. Firms are an apparatus for successfully and collaboratively engaging these. Objectivity, as much as possible, is our discipline's dominant metaphor, the realm of rational man theorizing – but permits no consideration of Knightian uncertainty or bounded rationality. Consequently a rigorous analysis must proceed on the assumption that the 'answer,' the optimum action, lies in the data. This makes strategizing 'trivial' in the sense that it does not manifest the identity, intention, imagination, and values of the strategist as a creative human agent. The analysis is dehumanized and abstracted from the world of socioeconomic action where real value is created. More fundamentally, it does not take the firm as an apparatus for creating economic value seriously; yet the whole point of business practice is to generate new value and seize some part of it and thereby advance the human condition.

Adopting Knight's notions of engaging uncertainty, strategizing becomes profoundly subjective, the process of applying personal judgment to generate and manage practices that manifest the will of the actors. The difference between the metaphors is stark. The 'rational man' based objectivist metaphor considers only what is known or can be discovered using the methods of natural science. The second takes off from the strategist's subjective engagement with selected knowledge-absences that seem to offer opportunities for profit. The first metaphor's process is well understood. Facts are gathered and computed. The conclusion is articulated into instructions that are issued to subordinates whose function is to implement them as closely as they are able. Their progress is monitored; problems are handed to specialists to 'reengineer' the process and its controls. The metaphor is mechanical, logical, and rigorous. The second metaphor's process is utterly different. Aside from the exercise of judgment about what to pay attention to, how to interpret what is known in the light of the firm's goals, and how to manage the resulting activity, the relationship between those making the choices and those transforming them into value are very different for the subordinates' judgment is drawn into the process rather than being dismissed.

Overall, strategizing is the process of regarding situations, gathering data, imagining possibilities, choosing goals and means, and communicating conclusions. Because everyone's knowledge and judgment is limited, strategizing calls for energetic and imaginative commitment and collaboration, getting all hands to the pumps, making many types of contribution, for a firm's situation is always full of uncertainties but also of potential, to be seen as a glass half full, awaiting being filled with new value, rather than a glass half empty, a result of being not fully known and predictable.

Abstract

Together with an impressively imaginative and productive cohort of University of Chicago-trained sociologists, Anselm Strauss is emblematic of the long-lasting fecundity of American symbolic interactionism and its major impacts on sociology, too often neglected today. Strauss' personal contributions are as extensive as they are diverse, covering an amazing range of areas: sociological theory, social psychology, urban sociology, sociology of occupations and professions, sociology of work, qualitative research methodology, sociology of organizations, and medical sociology. He also helped launch new subdisciplines including medical sociology and sociology of the body and of emotion. The concept of action is the Ariadne's thread, which weaves the work of Anselm Strauss together.

Together with an impressively imaginative and productive cohort of University of Chicago-trained sociologists (Freidson, Goffman, Becker, Davis, Roth), Anselm Strauss is emblematic of the long-lasting fecundity of American symbolic interactionism and its major impacts on sociology, too often neglected today. Strauss' personal contributions are as extensive as they are diverse, covering an amazing range of areas: sociological theory, social psychology, urban sociology, sociology of occupations and professions, sociology of work, qualitative research methodology, sociology of organizations, and medical sociology. He also helped launch new subdisciplines including medical sociology and sociology of the body and of emotion.

The concept of action is the Ariadne's thread, which weaves the work of Anselm Strauss together. There is action around personal and group identity (*Mirrors and Masks*, 1959; *Status Passage*, 1971), action around death (*Awareness of Dying*, 1965; *Time for Dying*, 1968; Anguish 1970, all with Barney Glaser), the action of various professional and nonprofessional groups negotiating order and change in organizations (*Psychiatric Ideologies and Institutions*, 1964, with Leonard Schatzman, Rue Bucher, Danuta Erlich, and Melvin Sabshin) and, more generally, the action of negotiation and other processual forms in the doing of social life (*Negotiations: Varieties, Contexts, Processes, and Social Order*, 1979), action to control the impact of new technologies and chronic illnesses on medical work (*The Social Organization of Medical Work*, 1985, with Shizuko Fagerhaugh, Barbara Suczek, and Carolyn Wiener), and action around the management of chronic illness in everyday life (*Chronic Illness and the Quality of Life*, 1975, with Barney Glaser; *Unending Work and Care: Managing Chronic Illness at Home*, 1988, with Juliet Corbin). This concept of action, accompanied by its structural environment (contexts and conditions, and social worlds and arenas), marks the specificity of his interactionist approach culminating in his last theoretical book, *Continual Permutation of Action* (1993).

Intellectual Genesis

Strauss was born in 1916 in New York and brought up in an 'ordinary' Jewish American family. His father was a high school teacher and his mother a housewife. He wanted to study medicine and took his bachelor's degree in biology at the University of Virginia (1939). However, along the way he discovered psychology and sociology. Eventually, he opted for sociology and took his master's and doctoral degrees at the University of Chicago (PhD 1945). At Chicago, Strauss was influenced especially by Herbert Blumer and Everett Hughes and the sustained presence of Mead, Dewey, Thomas, and Park.

From 1944 to 1952, Strauss taught sociology, first (until 1946) at Lawrence College in Wisconsin, then at Indiana University (until 1952). There, with his colleague Ralph Lindesmith, he worked on a social psychology textbook (*Social Psychology* 1949, now in its eighth edition). In 1952, Strauss returned to the University of Chicago as an assistant professor. Embarking on a new program of research dealing with occupations and professions, in collaboration with Hughes, he started with a study of art students and young artists. In 1953, at the request of Nelson Foote, he wrote a paper on social psychology for an edited book aimed at graduate students, never published. This paper, distributed in a mimeographed version under the title, "An Essay on Identification," became the first part of *Mirrors and Masks: The Search for Identity*. However, completing the book took 4 years as he wrestled to introduce a more structural dimension. As then developed in sociology, social psychology left very little room for interaction between the individual and organizations. Strauss then laid claim to a new sociological approach to identity through synthesizing symbolic interactional and social organizational perspectives into a workable, suggestive social psychology. He used the concept of identity not to define, but as a conceptual lever to reveal heterogeneous relationships between individual identities and group identities, and to establish explicit linkages between structure and interaction. This theme of identity through collective commitment persists throughout Strauss' work and informs other concepts, such as social worlds, negotiated order, and trajectory.

The book appeared in 1959. It is a major milestone in Strauss' intellectual trajectory. The theoretical basis for a number of themes in his subsequent work is sketched. However, the process of construction through abduction, taking back and forth between empirical materials and conceptualizing, is still absent from *Mirrors and Masks*. The first

elements of grounded theory were laid down in 1957 when he did his short, first 'real' fieldwork as part of the famous research program initiated by Hughes and carried out primarily by Howard Becker, Blanche Geer, and Strauss. Using comparisons among the different hospital services to which the young resident doctors were allocated in succession as a methodological tool, Strauss highlighted a period of reciprocal assessment among interns, residents, and the hospital's permanent medical and nursing staff. In each iteration, the shift to a new service gave birth to new structural contexts, requiring afresh the work of defining the social order in ongoing processes of negotiated assessment. Strauss integrated the idea of active individuals responding creatively to the situations they encounter with the fact that these responses, these individual and group actions, can only be analyzed as embedded in sets of prior conditions, which themselves influence the present situation. The present consequences of an action become, in turn, the prior conditions for actions yet to come. Capturing the flows of such trajectories and their consequences was his goal.

This study was Strauss' first step in an area of research – medical sociology – that he contributed develop to for the rest of his career. Strauss left the University of Chicago in 1958 to head a research project on psychiatric institutions, and in 1960 took a new post at the University of California, San Francisco (UCSF), where he established both the Department of Social and Behavioral Sciences and the Doctoral program in Sociology in the School of Nursing.

A Privileged Field of Research: Medicine and Illness

Psychiatric Institutions

In 1957 Strauss led an interdisciplinary research team in an ethnographic study of two psychiatric hospital departments deliberately selected for their major differences. This work – *The Hospital and Its Negotiated Order* (1963) and *Psychiatric Ideologies and Institutions* (1964) – offers a new framework for analyzing complex organizations. Conceptualized as sites of permanent negotiation, continuous processes of generating and acting upon tacit agreements allow organizations to function. The negotiations include unofficial 'working' arrangements, official decisions among the various professional and other groups concerning the overall strategy of organization, and ways of literally dividing up the work.

Parallel to this vision of organization, professions like medicine are analyzed as nonhomogeneous worlds constantly changing and composed of segments, each of which harbors different identities and ideologies concerning the specificity of their practices and their central activities (*Professions in Process*, 1961). The general organization of a profession is shaped by conflicts and competition among segments in movement and change. Numerous compromises are established by the representatives of the different ideologies of the professional segments involved both with other professional segments and with clients/patients as well. There are also microlevel negotiations regarding the philosophies specific to each person, linked to their individual biographies. Professions are thereby contextualized, and Strauss has integrated the mesolevel into his work. All of Strauss' later work assumes such meaningful heterogeneities.

Working on Death

Anticipating one of the major issues in American society, in collaboration with Barney Glaser, Strauss participated in opening up a new field of research – the management of death in hospitals. The question of interactions among dying patients, hospital personnel, and family members was at the core of their work. In a ground-breaking series of books and papers, they introduced major concepts now part of the contemporary stock-in-trade of sociology. First, a particular 'awareness context' is seen as patterning the mode of interaction around the dying person, who is also defined as an actor in the situation. Different possible combinations of 'who knows what' exist, characterizing different types of awareness contexts. These are organized around various dimensions such as the number of people involved, acknowledgment of the awareness (pretense or not), the degree of awareness, the object of the awareness (here the dying person), or the awareness that the others have of the object (*Awareness of Dying*, 1965). Each context of awareness characterizes different modes of interaction. Strauss and Glaser defined four major contexts: closed awareness, suspected awareness, mutual pretense awareness, and open awareness. For each, the social regulations and other structural conditions entering into the interaction were detailed. But Glaser and Strauss went further in their sociological treatment of interaction. At a theoretical level, they were preoccupied with changes that may occur during the trajectory of interaction, not only with interactional stability. So they also focused on "the tendency for interaction to move out of regulated social bounds and into new interactional modes." Their approach differed from that of Goffman, who examined interactions in terms of the social relations that subtly govern them and which, from his point of view, are therefore a direct incarnation of social order. In contrast, for Glaser and Strauss it is the indeterminate and problematic nature of interactions that holds attention.

The second set of concepts is linked to temporality. Dying takes time. This observation, less banal than it might appear, opens the way to a theoretical construct, which, associated with the concept of trajectory, continued to inform Strauss' work. Conceiving of death as a process allowed the authors to see it as a series of transitional statuses in a passage from life to death. By questioning the facts and comparing them with other situations of individual status passage, the authors defined the trajectories of death as a status passage and retraced its major dimensions. This immediately forces the researcher to place the discussion within the framework of a social structure. The study of trajectories of death in hospital organizations allowed Glaser and Strauss to advance the idea of a structure in movement (here the hospital), a structural process. Strauss later drew on this notion of flexible structuring to develop a conceptual network organized around one central point: the heterogeneous and complicated work necessary for the management of chronic illness on a daily basis.

Chronic Illness, Management Work, and Trajectories of Illness

Starting as a battle cry ("Chronic Illness", 1973) to draw attention to problems raised for the health system by the

growing prevalence of chronic illnesses and the technologies developed to deal with them, Strauss and his collaborators opened up a major new field for medical sociology and anthropology. Across multiple writings (including four books) around the concept of trajectory, they developed a dense theoretical framework for future research on medical work, patient work, and the experience of illness. Elaborated in two stages, this framework has at its core the notion of work defined as action.

Trajectories of Illness and Medical Work

The concept of trajectory, this time associated with chronic illness, refers "not only to the physiological unfolding of a patient's disease but to the total organization of work done over that course, plus the impact on those involved with that work and its organization. For different illnesses, the trajectory will involve different medical and nursing actions, different kinds of skills and other resources, a different parcelling out of tasks among the workers (including perhaps, kin and the patient), and involving quite different relationships – instrumental and expressive both – among the workers" (Strauss et al., 1985). This definition points to a transformation of the concept itself, moving from the substantive field of illness to the more general one of work. Work itself, a form of action, would become the center of the web of concepts organized around the concept of trajectory. From a sociological point of view, in Strauss' usual fashion, this concept is eventually understood to transcend the substantive setting and become a generic process and part of his version of 'formal theory.'

Thus, one of the first merits of the concept of trajectory is to remove the study of chronic illnesses from biological, medical, and psychological frames of thought and instead equip the researcher with a reflective stance based on analyzing the work involved – clearly and distinctively social phenomena. The initial framework of this formulation is a research monograph analyzing the combined impacts of chronic illness and new medical technologies on medical work in the hospital, *The Social Organization of Medical Work* (Strauss et al., 1985). The scene is complex: the illnesses are extremely varied (new technologies prolong the trajectories and even create new ones), and the work is carried out in different places in the hospital. This diversity can be conceptualized only by tackling the content of the work per se and its concrete execution. This is the juncture at which work and trajectory meet. Meticulous ethnographic analysis of the different types of work composing medical work is built up around the concept of trajectory to allow an analytic understanding of the organization and execution of the therapeutic work.

The trajectory of the illness can be seen as composed of series of successive, overlapping tasks, which, taken together, make up 'arcs of work.' The interaction of efforts to control the illness and the contingencies (predictable or not) shapes each trajectory. As an heir to the Chicago School, particularly Hughes, Strauss has a different way of looking at work. His point of departure, in fact, is neither the existence of a formal division of labor nor the problem of allocation of tasks. Quite the reverse. His central argument concerns the primacy of the work: The work processes themselves shape the division of work, as well as the experiences and the careers of the individuals doing this work, and influence the very structure of the organizations within which it takes place. Different types of medical work have been identified and analyzed: working with machines, working on clinical safety, the work of comfort, working with feelings, working on errors, working with the body, the work of information, the work of negotiation, and the work of articulation (Strauss et al. 1981, 1982b, 1985; Strauss, 1988, 1993; Corbin and Strauss, 1988). However, the types of work and their combinations vary across the overall trajectory of the illness and its specific arcs of work. Hence, the goal is to try to understand the links between tasks and workers as accountability chains.

Because the same task can be carried out by different actors, with different qualifications, at different moments of the trajectory, one of the essential analytic effects here is to establish a distinction between acts and actors. By basing the analysis not only on occupations and professions or organizational structures, but also on the work itself (its conception, organization, the concrete actions of doing it), concepts such as 'mistakes at work,' 'dirty work' (both Hughes' ideas), group work, and work with customers or clients are seen in a different light. Moreover, through this approach to work, Strauss brought to the fore the concept of invisible work, tasks that are requisite but usually ignored and usually carried out by lower level workers – nurses, psych techs, orderlies, janitors. Seeing all the work and workers gave him the means to make visible in the early 1960s the neglected work of technicians in psychiatric hospitals, an exploration that continued in the work on chronic illness.

This focus on the work itself has another major implication: it allows conceptualization of the patient as an actor in medical work and in the analysis of the different components of patients' work. In fact, patients are involved virtually throughout the work process, but their work is often difficult to identify if they are not systematically conceived as actors. The issue is not of so much knowing the patient's place in the division of work, as it is of understanding how the different types of work that she or he accomplishes fit into the overall work of the group and the relationships among their respective trajectories. In sum, for Strauss, work is synonymous with action. This concept of work is further developed in his final research projects.

The Work of Management: Biography and Trajectory

Triggered in part by his own massive heart attack, Strauss realized that the lion's share of the trajectory of a chronic illness takes place not at the hospital but at home, and the sick person is not the only person affected. Every facet of a person's life and these of his or her family and friends are implicated to differing degrees. The duration of the illness, the person's age, sex, and income bracket interact with the work of managing the new conditions of life brought into existence by the illness. In his last empirical project, in collaboration with Juliet Corbin, Strauss analyzed the dimensions of the work of management carried out every day by couples in which one of the spouses is afflicted with a chronic illness or disability (*Unending Work and Care: Managing Chronic Illness at Home*, 1988). Here he deployed a complex theoretical web linking trajectory and

biography with work conjugated as action starting from the experiences, which people afflicted with a chronic illness go through – especially the sense that their bodies have betrayed them. Leaving behind problems of body image or psychological and psychiatric concepts of stress and coping, he focused instead on biographical work processes – an idea rooted in fieldwork. An illness is always placed in a biographical context: what happened before, what life was like in the past, what hopes and dreams had been shattered or altered. For Strauss and Corbin, a biography is made up of three elements: biographical time, concepts of the self, and the body. For each aspect of himself or herself, a person must accomplish various groups of tasks in relation to biographical management. All these tasks fit into biographical time, since they are part of this individual's past, present, and future.

The accomplishment or execution of these tasks linked to the self requires that the body functions in appropriate ways. Through the expression biographical body conception, Strauss and Corbin sought to conceptualize the interdependence of these three elements: conceptions of the self (identity) are generated directly or indirectly through the body and evolve in line with the unfolding of biographical time.

The structural conditions arising from the illness – the individual biography and everyday life on the one hand, and on the other, more general political, social, and economic conditions – together influence the effectiveness, speed, and even the mood in which the work is done. The structural backdrop against which trajectory management takes place is important because of its implications for this work. The immediate interaction is combined with close and distant structural conditions to create a work context. The context then throws light on the core of the action by showing how interaction becomes the means whereby the work itself is accomplished under different – and specified – conditions. In this sense, structure and interaction are intimately linked.

The Web of Negotiation and Social Worlds

Drawing on his work on professionals and hospitals, Strauss progressively developed theories about social space and social relationships. It is important to stress that these theories simultaneously nourish the work presented so far and are also generated by it, as this is distinctive to Strauss' way of thinking. He continued this vein of work in his book *Negotiations: Varieties, Contexts, Processes and Social Order* in 1979. Here he proposed a "paradigm of negotiations," a grid for analyzing negotiation processes, and applied it to a wide range of case studies. In the development of this paradigm, we find the same theoretical leverage point as in all of Strauss' research. He starts, as in his analysis of work, from the negotiation itself and its secondary processes (e.g., bargaining, obtaining gratification, paying debts, and negotiating agreements), interactions, types of actors, their strategies and tactics, and proceeds to examine the consequences. He then builds a context of action on two levels: on the one hand, the structural context within which the negotiations take place and, on the other hand, the context of negotiation that refers specifically to structural properties acting directly as conditions on the flow of negotiation. Strauss uses this context of negotiation as he used contexts of awareness: "Just as there are many types of awareness context pertaining to interaction with respect to dying persons, so also there are many specific types of negotiation context pertaining to interaction among negotiating parties." These different types can be reconstituted in terms of the combinations of the general properties of any negotiation context.

The importance given to negotiation in social life is not surprising in a sociologist who always sought to empirically address one of the fundamental tensions of sociology: that between constraint and freedom, and to do so with attention to range of variation. Strauss' analysis of society as composed of social worlds and arenas is closely associated with this preoccupation. Moreover, this demonstrates his desire to uphold the central position of Thomas and Park on social change – that it is produced by the shock and encounters of groups, by the reciprocal effects and reactions of groups of all kinds encountering each other and their attempts to deal with such encounters (see also Blumer, 1958). Strauss formed a loose map of the territory to provide a perspective in terms of social worlds: "We are confronting a universe marked by tremendous fluidity; it won't and can't stand still. It is a universe where fragmentation, splintering, and disappearance are the mirror images of appearance, emergence and coalescence."

The strength of this approach comes not from defining in advance either the actors in social worlds or their conventions but, on the contrary, from the attempt to empirically identify and represent them. Thus the approach opens up questions of boundaries of the social worlds and the 'authenticity' of what is produced (whether it is a work of art or a medical treatment). This perspective is deeply attuned with analysis of a 'project' or a trajectory, as described above. In two successive articles, Strauss (1982b, 1984) frames various processes of segmentation of social worlds, their interaction through processes of intersection, and processes of legitimation or recognition as developed in this kind of 'social matrix.'

The development of ideas initiated decades earlier culminates in Strauss' capstone book, *Continual Permutation of Action* (1993) in which he offered his own interactionist theory of action. Reviewing the trajectory of his life work through the lens of action, he made clear that action for him is synonymous with acting and he redefined this perspective of negotiated order using a verb rather than a name "processual ordering," stating that "this concept of processual ordering of reactivity is meant to embrace every main topic discussed in this book and of course many more." In what can be described as a theoretically grounded legacy, he gently and firmly gives us important means to participate as sociologists and human beings in this ever-changing world with our own sociological awareness.

Grounded Theory and Thinking through Fieldwork

Strauss is perhaps internationally known best for his work in qualitative research methods. In the postwar era, quantitative procedures were the most commonly used methodological tools in the 'social world' of American sociology, though it was possible to see the beginning of a renewed interest in fieldwork. Glaser and Strauss (1967) gave this movement significant

momentum with their now famous book *The Discovery of Grounded Theory*, which sought to legitimize qualitative sociological research. The book was and remains a benchmark for qualitative sociology. Over and above the deeper investigation of methodological issues, in *The Discovery of Grounded Theory* one finds a concept of sociology as a discipline centered on and through prolonged fieldwork. Qualitative analysis can generate the only kind of theoretical statements they saw as legitimate: 'grounded theoretical statements' derived from painstaking field studies. Theoretical generalization remains possible, but only when based in empirically rooted statements.

The singularity of this approach resides in the deliberately reflexive style of the analysis and the rhythm at which the research proceeds, along with the reasoned (if highly unusual) overlapping of its different stages. From its first formulation, two aspects of grounded theory make it unique: (1) analysis must begin as soon as there are data and (2) variations in the data must be looked for through 'theoretical sampling,' that is sampling observation sites or persons to find new data on emergent ideas and concepts. The goal is to force the researcher in an organized way to generate ideas, thinking through fieldwork. In *Qualitative Analysis for Social Scientists* (1978), Strauss presented a loose 'coding paradigm' around concrete examples taken from his own research and that of others in 'working groups' or analysis sessions that he led weekly. This book is itself a living ethnographic testimony to how Strauss taught and worked. Procedures for analysis have been developed in a series of basics books (1990, 1998, 2008).

Strauss' Influence on Social Sciences and Beyond

With more than thirty books, many translated into other languages, and over hundred articles and chapters, the impact of Anselm Strauss is impressive and lasting. Moreover, Strauss crossed boundaries in at least two ways: across academic disciplines (sociology; social psychology; anthropology; linguistics; nursing; education; social work; communication; cultural studies; etc.), and specialty areas (work, professions and occupation; heath and illness; urban sociology; organization studies; etc.). He deliberately wrote for multiple audiences.

Not only was Strauss one of the founders of the specialty of medical sociology, but he was ahead of his time in two major areas, contemporary studies on death and dying (in sociology, in nursing, medical, social work, physician professional spheres, and bioethics) that still draw on Glaser and Strauss' conceptual framework 50 years later. Second, Strauss and his coauthors work on the sociological study of chronic illness laid the ground work for all future studies on 'the experience of illness,' influencing research directions in sociology and anthropology, and beyond. Strauss pioneered a radical understanding of patients and kin as active people, not passive. His conceptualization of the work of patients and their families was a profound breakthrough that not only changed sociological research but also influenced the political economy of health. Moreover, it enlarged political debate about physician–patient relationships and legitimated patient empowerment in the vein of the Chicago tradition. This exemplified the professional and personal commitments of Strauss toward improved and more democratic participation of lay and sick persons in the health system.

Strauss' perspectives on identity, social worlds and arenas, and negotiated ordering have penetrated many specialties including social studies of science and technology through some of his students' works (Star, 1989; Bowker and Star, 1999; Clarke, 1998; Clarke and Star, 2007; Fujimura, 1996.) Grounded theory is today the most cited qualitative approach globally (Clarke and Charmaz, 2014). While sometimes used superficially, it is also a living tradition, and groups of researchers continue to embrace its reflexive position and work at deepening and also expanding it (Charmaz, 2014). Adele Clarke (2005), a former student of Strauss, created an extension, which integrates aspects of postmodernism, supplementing basic grounded theory with a situation-centered approach.

The depth and diversity of Strauss' intellectual contributions will continue to have long-term impacts on sociology and beyond, highly visible and less visible.

Street Children: Cultural Concerns

Elizabeth A Swart, University of Southern California, Los Angeles, CA, USA

This article is a revision of the previous edition article by C. Panter-Brick, volume 22, pp. 15154–15157, © 2001, Elsevier Ltd.

Abstract

This article reviews contemporary literature on the so-called street children. There has been a paradigm shift since the late 1970s in the way social scientists understand and seek solutions to the global problem of street children that abandons misleading categorizations of street children for highly contextualized studies that emphasize the heterogeneity, agency, and gender of the population. This article seeks to understand culturally constructed intersections and the associated material conditions within which children negotiate their own identities. To this end, participatory methods and intervention models help situate the discourse in historical and ethnographic context.

Introduction

Since the late 1970s, there has been a paradigm shift in the way social scientists conceptualize 'street children.' Although governments and the media continue to refer to street children as an undifferentiated group or to categorize them in misleading ways, e.g., by differentiating between children 'in the street' and 'of the street,' contemporary research emphasizes the heterogeneity, agency, and gender of street children and this has given rise to unique research questions and participatory strategies for aid and intervention.

Definitions

Defining 'street children' has itself been problematic. The term 'street children' is still used by many as though there are two (but only two) categories of children – 'street children' who are without homes and families and 'normal children' who are not – thereby creating a false dichotomy that belies the heterogeneity of the population of street children, ignores issues of social construction and cultural context, and overlooks the many lines of differentiation that exist among street children.

In 1979, the United Nations 'Year of the Child,' the term 'street children' was popularized to designate the growing population of young people who spent some or all of their time in urban public spaces. Although the designation was meant to neutralize negative terms then in common usage – street urchins, vagrants, street Arabs, ragpickers, and the like (Panter-Brick and Smith, 2000) – it did not solve the definitional problem. In fact, it was only the beginning of an ongoing debate about how to define, delimit, and desensitize the discussion about this controversial population, the conception of which is closely related to cultural understandings of urbanization, homelessness, and structural issues related to poverty.

In 1983, the Inter-NGO Program for Street Children and Street Youth came up with a new slant on the definition, dubbing street children as "those for whom the street (in the widest sense of the word, that is, unoccupied buildings, wasteland, etc…) more than their family has become their real home, a situation in which there is no protection, supervision, or direction from responsible adults" (Ennew, 1994: p. 15). The definition led to calls for clarification of terms like 'protection,' 'home,' and 'family' (Hecht, 1998) because such terms have a great range of meaning, both historically and culturally. Critics pointed out, for example, that the term 'home' may refer to a situation of affiliation with other people or to transience, instead of access to a physical abode, as the notion of 'home' is usually understood in Western scholarship (Desjarlais, 1996).

Responses attempted to recognize various *categories* of street children and to clarify the heterogeneous nature of the population. These, too, proved confusing. The United Nations International Children's Emergency Fund's (UNICEF's) notion of categorizing children as 'of the street' or 'on the street' presented a seeming solution. According to this definition, children *of the street* made the streets their home in a consistent and constant manner. Children *on the street* (or *in the street* in an alternative but equivalent formulation) were those who had families to return to but often worked on the streets or chose to be there for periods of time before returning home. Other attempts were made to categorize street children by their 'degree of family involvement' or their 'psychological characteristics' (Panter-Brick and Smith, 2000). But such attempts at categorization raised semantic and definitional issues because they were neither analytically precise nor culturally grounded in dealing with the fluid and ephemeral nature of street child populations (Panter-Brick and Smith, 2000). By the beginning of the twenty-first century, the discourse had turned from *categorization* of street children themselves to the *contextualization* 'of their position in particular cultural situations' and how the concept of street children is structurally related to regional issues of homelessness and poverty (Panter-Brick and Smith, 2000: p. i). For example, research began to recognize that "abandonment in its most recent manifestations may include a wider range of childhood experiences than explored" previously and that the discussion is embedded in a historical context "when changes in family form, attitudes to sexual identity and reproductive technology" united to put both concepts of child and home, and even parent, into question (Panter-Brick and Smith, 2000: p. xv). As society began to consider children more subjects of human rights than objects of concern (Ennew, 1994), the

implications for research, policy, and intervention also shifted enormously, reflecting less a welfare-based understanding of street children than a growing concern that research correctly portray these children's views of themselves and their relationship to society. Although the term 'street children' is still widely used by governments, nongovernmental organizations (NGOs), and helping agencies to refer to youth who occupy urban public spaces, many categories such as 'of the street' and 'on the street' have lost credibility. Social scientists have moved the debate beyond overly facile noncontextualized categorization and into issues of diversity and intersectionality. The latter refers to systematic study of the interactions of multiple systems of oppression, e.g., race, class, gender, etc.

Twenty-first century research on street children has become increasingly focused on (1) the concept of street children as a socially constructed one, (2) the cultural understanding of poverty and homelessness, (3) the need for longitudinal studies that describe lifetime career outcomes of street children's lives, (4) the development of participatory research methods, and (5) the development of effective research strategies that foster children's human rights (Panter-Brick, 2002). With these changes came a new interest in the intersections of age, gender, class, ethnicity, sexuality, and ability as these variables relate to street children, their coping strategies, and life-course paths (Beazley, 2002; Evans, 2006).

History

Abandoned and homeless children have doubtlessly been present since the beginning of civilization, appearing sporadically and tangentially in Western histories since Roman times. In fact, Western historians note that street children made up the largest population of boy prostitutes in Augustan Rome (Boswell, 1988). Similarly, in CE 422 – anthropologists use CE (Current Era) – a church council expressed concern that street children were treated with ruthlessness and violence (Boswell, 1988). Street children were common in Russia, both under the Tsarist rule and after the Russian Revolution.

In both Britain and the United States, the industrial revolution affected families in a variety of ways, contributing to rural–urban migration, child labor, family disruption, caregiver death, and the phenomenon of working, abandoned, or homeless children. In 1848, Lord Ashley remarked that there were at least 30 000 "naked, filthy, roaming, lawless, and deserted children" in metropolitan London (Hutson and Liddiard, 1994). Near the turn of the twentieth century, American photographer and social historian Jacob Riis captured images of huddled children sleeping on streets adjacent to tenement houses in New York in his shocking *How the Other Half Lives* (Riis, 1890). World War I further increased the number of street children, especially in Russia where, by 1922, there were an estimated 7 million homeless children (Ball, 1996).

After World War II, the presence of homeless children on the streets of Western Europe prompted United Nations Educational, Scientific and Cultural Organization in 1951 to utilize the term 'street children' to define this growing social problem. In the 1970s, the United Nations Year of the Child (1979) brought attention to the growing street child population and popularized it as a social cause, thereby rendering the term 'street children' as a call to action and intervention. By 1986, UNICEF was raising alarms about the growing population of homeless youth in the *developing* world, citing skyrocketing numbers in India, Brazil, and Thailand. Today, street children, particularly those in the developing world, are often residents of huge slums, adjacent to large metropolitan areas. In these 'megaslums,' street youth are especially vulnerable to prostitution and survival sex, addiction (to glue or toluene, changa'a, and petrol), sex trafficking, and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) infection (Wittig et al., 1997; Davis, 2006; Swart, 2009).

Throughout the twentieth century, the social construction and understanding of 'childhood' have played into our representation of street children. The Western discourse on childhood posits that the street is not an appropriate place for a child and the child who is on the street is 'out of place,' socially deviant, or in dire need of intervention (Boyden, 1990; Hecht, 1998). Ennew has pointed out, however, that such a dichotomous understanding of the population – as either victim or villain – is unhelpful because it "tends to ignore social networks and coping strategies developed by the children" (Ennew, 1994; Panter-Brick and Smith, 2000). Social scientists today are engaging in child-centered research perspectives that are likely to yield more accurate data about populations of street children, as well as more meaningful interventions.

Statistics

In the late 1980s, UNICEF estimated there were about 100 million 'street children' around the world. In 2005, it admitted what a moment's reflection makes obvious, namely, that "the exact number of street children is impossible to quantify." UNICEF, as of 2012, will say only that there are "tens of millions" of street children around the world and that the numbers are increasing (UNICEF, 2012). The 100 million estimate is still commonly cited by researchers and policy makers because attempts to more accurately estimate the population of street children are frustrated by the fluidity of the population and differing agency and governmental agendas. When NGOs issue divergent estimates, it is sometimes because, according to Panter-Brick, they were not talking about the same children. That is, the definition of street children is embedded in the social construction, maintenance, and management of homelessness as a social problem (Ennew, 1994; Panter-Brick and Smith, 2000) and with how it is defined and quantified in various contexts.

Gaps in the Research

Judith Ennew was perhaps the first to insist that most national and regional estimates of street children "had no basis in fact" (Ennew, 1994: p. 32) because they were "rarely referenced to counting methods" (Thomas de Benitez, 2011). Although Ennew asserted in 1994 and in 2000 that "the arithmetic" used to arrive at estimated street child numbers "is as symbolic as the children themselves" (Ennew, 2000: p. 170), the 100 million number was still commonly referenced in articles and academic journals and remained in common usage for more than two

decades. Experts today are more cautious in their 'guesstimates,' using the tens-of-millions estimate as a go-to figure that is neither overblown nor understated. Nevertheless, more precise numbers – and the methodologies that produce them – are emerging.

Improving Localized Counting

Throughout the 1990s, collaborations between UNICEF and governments at the national or city level yielded rapid situation assessments that were, unfortunately, not tied to uniform methodologies or definitions. The lack of definitional and methodological uniformity led to an outpouring of 'head counts' that, when considered together, were either misleading or nonsensical. In 1989, for example, UNICEF estimated that 100 million children were on the streets of the world's major cities, while two other estimates claimed (for Brazil alone) 20 million (Connelly, 1990) and 50 million (De Moura, 2005), implying that nearly half the world's street children are Brazilian, which one researcher remarked seemed 'rather unlikely' (Marrengula, 2010).

Since the beginning of the twenty-first century, though, efforts to count street children have "become more careful in their research methods and more circumspect" in their estimates (Thomas de Benitez, 2011: p. 5). Efforts today are yielding improved localized counting, made possible in part by a new definitional understanding of the 'street connectedness' of children (Thomas de Benitez, 2011: p. 5). Defining children as 'street connected' permits tossing the dichotomous 'on the street' or 'of the street' thinking into the rubbish bin, along with the temptation to *categorize* children in misleading and unhelpful ways. Instead, using a definition that emphasizes 'street connectedness' – that is, defining street children as those who depend on the street as a *central reference point* in their lives – adds both a broader cultural base to the definitional debate, as well as a sharper focus on individualized context. The concept of 'street connectedness' sheds light on the 'multiple deprivations' of street children within a global context, while it also situates street children 'within the wider policy agendas and interventions' of particular cities and countries (Thomas de Benitez, 2011).

Definitional improvements are accompanied by innovative and extremely localized data collection, using participatory research to help determine local numbers. For example, Ensing and Strehl's (2010) study of street-working and street-living children in Peru used local knowledge and local investigators to determine numbers of street children in Cusco and Lima. Their methodology consisted of a 35-question survey administered by six enquirers to 343 street children, who were recruited through painstaking and personalized knowledge of the children themselves and their locale:

> The enquirers responsible for approaching and interviewing the children in Cusco were all Peruvians living in Cusco. They were male and female, students and graduates, between 22 and 34 years old. Most of them had experience in working with street children or working children. The enquirers worked in couples and were scheduled to work in one specific area only. This way, they could become familiar with the neighborhood and the children on the streets. (Ensing and Strehl, 2010: p. 3)

Similarly, Marrengula (2010) used localized, participatory research to determine numbers of street children in Maputo, Mozambique. After allying themselves with a local NGO known to and trusted by street children, Marrengula's team constructed a methodology that they hoped would provide the most accurate head count possible for the city. It consisted of visiting street children's 'zones' at night, something local helping professionals, being used to providing services to children during the daytime, had rarely attempted. Marrengula describes precise, localized methods for determining numbers:

> The research team…came to a consensus that it was very worthwhile to work during the night, as most of the street children were working during the day, and we would not have any information about their real location during the day and this idea would give us a close to real picture of the social landscape of the street children in terms of their numbers and group members…. (Marrengula, 2010: p. 139)

The head count was accomplished "first by making several rounds of the city area, then making several visits to different places where children had been living and asking those children about the location of other places" street children lived (Marrengula, 2010: p. 143). Researchers walked long distances around the city during late evening hours, working from 7 to 10 p.m. 3 days a week for 5 weeks to gather information about children living in each *zone*. The data collection team asked authorization to visit the children at night. Once that was given, they began discussions with children about their lives, feelings, and problems. With the help of children, other zones were determined where the same methodology was put into place:

> We had to visit each zone two or three times in order to make sure the information gathered on previous visits matched, because it happens that those children moved constantly or that they provided false information about the group. During these visits, we attempted to gather information that could give us detail in the following aspects: number of children in the zone; the name used to identify the zone; the names of the street children; and, if possible, their ages, their interests, their difficulties and challenges. (Marrengula, 2010: p. 143)

During the course of the study, Marrengula's team identified "five communities of street children with a total of 42 zones where 445 street children were living, of which 46 were girls and 5 were babies under 2 years old" (Marrengula, 2010: p. 145). This number and its demographic diversity had heretofore *not* been known (or had been underestimated) by local NGOs, even those with a close relationship to the city's children.

As of this writing (in 2013), research aspires to definitional *and* methodological uniformity and transparency. Some progress is being made. Nevertheless, major gaps still exist in research methodologies and data collection. The Consortium for Street Children (Thomas de Benitez, 2011) has pointed out several of the most egregious gaps in research about street children. For example, academic research about street children is 'fragmented' (Thomas de Benitez, 2011: p. ix), being

conducted in a variety of disciplines and departments without consultation or collaboration. Thus, much of the data remains in "small islands of research within separate disciplines" (Thomas de Benitez, 2011: p. ix), which are not informed by one another and are often used at cross purposes. Similarly, academic and *development* studies are also conducted without reference to one another, meaning that academic knowledge "rarely informs development practice and vice versa" (Thomas de Benitez, 2011: p. ix). Finally, experts contend that "no motor exists for the building of a body of research on street children" and that a concerted effort is needed to coordinate interdisciplinary research and to make data available in a proactive way to relevant audiences.

Agency

The issue of children's agency has become an increasingly important concept since the beginning of the twenty-first century, with participatory research being used to improve numbers' estimates and to enhance our contextual understanding of street children's lives. Panter-Brick has pointed out that in the late 1990s, fundamental assumptions about children and appropriate methods of research began to be reevaluated in the context of international laws about children's rights (2002). A growing awareness developed in the social sciences that children were not helpless victims but capable agents, able to make informed choices about their lives and future aspirations. Researchers attempting to view street children's lives from the children's own perspectives have recognized children's agency, competence, and participation in their own life choices. A partnership methodology has emerged, in which social scientists design projects that work 'with' children not 'for' them and view that children are "not objects of concern but people … who need respect, not pity" (Ennew, 1994: p. 35). Such participatory research has given rise to reflexive methodologies that are perhaps more effective than the commonly used questionnaire (Panter-Brick, 2002), such as participant observation, group workshops and discussions, in-depth interviews, and innovative techniques, such as encouraging children to draw, act out, and 'map' their own life experiences (Young and Barrett, 2001; Beazley, 2002; Evans, 2006). Although these methods have drawbacks, many social scientists have found that they yield data that more accurately reflect the experience of street children as seen through the children's own eyes (Beazley, 2002; Evans, 2006). These data are, therefore, more potentially helpful in understanding the fluidity of the population and devising culturally specific interventions.

Gender

The dramatic rise in the number of street girls, particularly since the mid-1990s, has resulted in a more *gendered* discourse about street children. Several important issues arise in the discourse on street girls: they are doubly marginalized in terms of social attitude and the dominant discourse on gender and they are more vulnerable to discrimination and to sexual exploitation on the street; but, nevertheless, many street girls subvert dominant paradigmatic gender constructions to create their own gendered spaces on the street. For example, street girls may select and maintain boundaries around their own social spaces where they gather with one another, excluding male street youth. Beazley has observed that, in their own gendered gathering spaces, street girls in Indonesia are "more vocal, gregarious, and confident" (Beazley, 2002: p. 1675). Such gendered spaces insulate and protect street girls from discrimination at the hands of both the dominant culture and male street youth.

Research on street girls has revealed that girls' double-marginalization is defined in terms of social attitudes toward deviance. Girls suffer discrimination not only for being *children* on the street but also for being *females* in a place not traditionally defined as acceptable for them. Lucchini has described the predicament of street girls in Argentina by saying

> The street world is before all masculine. The presence of girls in the street upsets the values and representations of adults. Uneasiness takes place and the explanation of this presence goes through a pathologizing of the girl and her family. The marginal girls and the delinquent girl are soon associated to sexuality. (Lucchini, 1994: p. 8)

In Indonesia, for example, street *children* are referred to as 'tikyan' (a generalized category referring to homeless youth) but street *girls* are called 'rendan,' or 'other' by street boys, who use the designation to stigmatize female street youth (Beazley, 2002).

Furthermore, street girls suffer from higher vulnerability to sexual abuse on the street, both from society in general and from street boys, who find in street girls a group they can dominate and control. Research in Indonesia, for example, reveals that:

> …street girls particularly encounter abusive discrimination on the streets of Indonesia because they are seen to be committing a 'heretical geography' by violating ideas of femininity in state discourse and by 'invading' the street that is fundamentally a male space….Although street boys are themselves powerless children, suppressed by the control of an oppressive regime, street girls are one group to whom them feel they are superior and over whom they have power. (Beazley, 2002: p. 1679)

Girls also suffer from lower income-generating potential on the street, where the division of labor is highly gendered. While street boys engage in odd jobs, scavenge for salable items, and wash car windows (in many urban cities, such as Nairobi and Kampala), street girls are confined to labor that is defined as appropriate for females, e.g., laundry, house-cleaning, food selling, and the selling of sex. Such jobs are less lucrative and, in the case of prostitution and 'survival sex,' more dangerous, since the girl risks pregnancy, as well as sexually transmitted diseases including HIV/AIDS infection (Swart, 2009, 2012).

Nevertheless, many of these girls actively subvert gender norms (Beazley, 2002; Evans, 2006) to construct their own gendered identities and their own gendered sense of place (Beazley, 2002; Evans, 2006). For example, in Indonesia,

"street girls negotiate social and personal spaces that are different from those of boys …. These socio-spatial patterns are explained as 'geographies of resistance,' which are a response to the pervasive patriarchal discourse within Indonesian society, a society which believes that girls, in particular, should not be on the streets" (Beazley, 2002: p. 1665). For example, girls create their own gathering place in a city park, where they gather with other girls, sleep, keep possessions in a small building by the park gate, and generally 'hang out.' By contrast, street boys gather in the city center, near a public toilet. Girls also create their own style and behavioral patterns, including adopting short hair cuts, wearing men's shirts, and adopting behaviors, such as smoking and body piercing, which run counter to accepted gender norms. Street girls also create their own patterns of negotiating social space, which involve not only separate 'hangouts' from those that boys use but also different *patterns* of movement (in smaller groups than boys) and *times* of within-city movement (night instead of day) (Beazley, 2002: p. 1677). Similarly, in Tanzania, Evans has discussed how young people "reconfigure gender norms and the concept of 'family' on the street" (Evans, 2006: p. 109) and how girls "actively subvert gender norms by seeking independent lifestyles in towns and cities" (Evans, 2006: p. 125). While street boys sleep in gutters, bushes, or verandas, for example, girls often team up with other girls or boyfriends to stay in guesthouses or other temporary shelters that afford them protection from the street. Within such settings, Evans' study of girls' photographic accounts of their lives show them playing a variety of gender roles in temporary domestic settings – washing dishes, playing with children, dressing in Western-style clothes, looking 'tough,' and putting on evening makeup. Girls present a variety of *selves* in pseudo-domestic street environments, sometimes even parodying dominant paradigms, such as motherhood, homemaker, or prostitute by overemphasizing the stereotypic characteristics of that role, such as wearing excessive lipstick to parody the prostitute image they deplore (Evans, 2006). For such girls, the street presents an opportunity to "construct their own gendered places, where identities are contested and negotiated, and where stigmatizing labels and restrictive norms can be resisted and reconfigured" (Evans, 2006: p. 125).

Responses and Solutions

The Human Rights Discourse

A strong and pervasive discourse on children's human rights began when the United Nations Convention of the Rights of the Child (1989) articulated a set of acknowledged rights for children worldwide and shifted the discourse from the needs of street children to their *rights* (Panter-Brick, 2002: p. 155). Thus, the dialogue shifted from one characterized by humanitarian pity (children's needs) to one seeking to empower children with their rights as citizens (Ennew, 1994). As the paradigm shifted from understanding children as victims to perceiving them as rights-holding citizens, social scientists began to view children as agents of change with power over their own lives. This new interest in children's agency, participation, and point of view gave rise to new research questions and strategies.

Participatory Methodologies and Partnership Ethics

One response to the human rights discourse has been to find alternatives to unhelpful and inaccurate categorizations of street children by focusing on the *diversity* of experience within the street children population. To that end, research about street children has become vividly descriptive and more broadly focused on intersectionality. Current research is increasingly focused on street children as a highly differentiated group and on the ways that "their differences affect their experiences" (Beazley, 2002; Ennew and Swart-Kruger, 2003; Ruvero and Bourdillon, 2003; Evans, 2006). The understanding of this intersectionality of age, gender, ethnicity, class, and ability enables social scientists to articulate meaningful differences within a heretofore (seemingly) monolithic population.

There has also been a marked increase in participatory research methods and child-centered research. For example, one study on the negotiation of social identity among street children in Tanzania used "participatory methods, such as focus groups, drawings and photographic exercises" (Evans, 2006) to engage young people in the research. Others have used such child-centered methods to give children more control over the representation of their lives (Young and Barrett, 2001).

Research on street children has also articulated a partnership ethic in relation to the population being studied. Instead of doing research 'on' street children, social scientists conduct research 'with' street children, using such methods not only to engage children in the research but also to enable them to participate in describing their own lives (Evans, 2006; Beazley, 2002).

Interventions

Social scientists in the twenty-first century seek responses and solutions that are contextual and tailored to individual subpopulations of children. Recognizing both the heterogeneity of street children around the world, as well as the necessity of adapting interventions to unique populations, social scientists are creating unique intervention models for specific populations, such as refugee children (Hinton, 2000), slum children (Montgomery, 2000; Swart, 2012), children displaced by war (Charnley, 2000), and many more. For more examples of contextualized intervention models and strategies, see Panter-Brick and Smith (2000) and Subbarao and Coury (2004).

Stress and Cardiac Response

Abstract

The notion that organisms react physiologically to danger and that this reactivity represents a long-term health risk, is essential to the concept of stress. This article summarizes the literature on cardiac defense. This article begins with a brief introduction to the physiology of cardiac reactivity. Then it focuses on the history of the two major research traditions in the study of cardiac defense: the cognitive and the motivational. It then presents a new approach to the study of cardiac defense based on the analysis of the complex pattern of heart-rate changes elicited by intense auditory stimulation.

The origin of the concept of stress in health-related disciplines is closely linked to the idea that organisms react physiologically to danger or threat. This reactivity has a protective function since it provides the logistic and instrumental basis for adaptive behaviors such as fight or flight. However, if maintained for long periods, this protective or defensive reactivity may become a health risk, compromising the normal functioning of the organs involved. For many scientists, the excessive physiological reactivity associated with stress is the main mechanism linking stress to illness.

Cardiac Response

The heart is a vital organ that reacts rapidly to physical and psychological demands. This reactivity is controlled by the central nervous system through neural and humoral pathways.

Neural Pathways

The neural pathway to the heart involves the two branches of the autonomic nervous system: the sympathetic and the parasympathetic. When the sympathetic nerves are activated, the heart rate accelerates and the heart contraction becomes stronger, resulting in a greater blood volume discharge and greater blood pressure in the vessels. When the parasympathetic nerves are activated, the heart rate decelerates, reducing the blood volume discharge and the blood pressure. The two branches can act reciprocally (one activated and the other inhibited), working in the same direction (increasing or decreasing the heart activity), or nonreciprocally (both activated or inhibited simultaneously), competing against each other for the final cardiac outcome.

Humoral Pathways

The humoral pathway involves the neural activation of the endocrine system, resulting in the secretion by the adrenal glands of various hormones into the bloodstream. One of these hormones, adrenaline, when it reaches the heart, has the same effect as the sympathetic nerves: it increases the heart rate and the stroke volume. Other adrenal hormones, such as cortisol, facilitate the transfer of lipids and glucose into the bloodstream and also have an important indirect effect on the heart and on the arteries that supply blood to the heart muscle: the coronaries. The humoral effects on the heart are slower than the neural effect but they last longer, contributing to maintaining cardiac reactivity during prolonged periods.

Cardiac–Respiratory Interactions

Both the cardiovascular and the respiratory systems are responsible for maintaining the continuous exchange of gases, oxygen, and carbon dioxide between the atmosphere and the tissues. The cardiovascular system reacts to changes in the concentration of these gases in the blood. Therefore, changes in the respiratory pattern, which induce changes in gas concentration, produce changes in the blood flow and cardiac activity in order to restore the appropriate gas concentration. Two examples of cardiac reactivity due to changes in respiration are the hyperventilation and respiratory sinus arrhythmia phenomena.

Hyperventilation

Hyperventilation is caused by rapid respiratory patterns provoking reduced carbon dioxide concentration in the blood. The cardiovascular response is a reduced blood flow to the brain and heart arteries, and an increase in cardiac activity due to parasympathetic inhibition.

Respiratory Sinus Arrhythmia

In contrast, respiratory sinus arrhythmia is caused by slow and relaxed respiratory patterns. The consequence is a rhythmic deceleration of heart rate, due to parasympathetic activation, coinciding with each expiratory cycle.

Stress and Cardiac Defense

Cardiac defense can be defined as the cardiac response to a perceived danger or threat. The concept of defense has a long tradition in physiology and psychology and it is in this context that the concept of stress was first introduced.

Historical Antecedents

At the beginning of the twentieth century, Ivan Pavlov and other Russian reflexologists used the term defense reflex to refer to protective physiological responses elicited by noxious stimulation, such as hand withdrawal from an electric shock, eyeblink to a puff of air, or vomit to bad food. A few years later, Walter Cannon used the term defense to refer to the 'fight or flight' response, a sympathetically mediated cardiovascular response to emergency situations aimed at providing energy supply to the body to facilitate adaptive behaviors such as attack (fight) or escape (flight). By the middle of the century and following Cannon's ideas, Hans Selye had introduced the concept of stress and used the term 'alarm' response to refer to the first stage of the physiological response to stressful situations.

Classical Approaches to Cardiac Defense

There have been two major approaches to the study of cardiac defense: (1) the cognitive or sensory processing approach built on Pavlov's distinction between orienting and defense reflexes and (2) the motivational or emotional approach built on Cannon's ideas on the fight or flight response.

The Cognitive Approach

The cognitive approach assumes that cardiac changes to environmental stimuli reflect attentional and perceptual mechanisms aimed at facilitating or inhibiting the processing of the stimuli (Sokolov, 1963; Graham, 1979). The orienting response (a deceleration of the heart rate to moderate or novel stimulation) facilitates attention and perception of the stimuli, whereas the defense response (an acceleration of the heart rate to intense or aversive stimulation) reduces attention and perception as a form of protection against the aversive stimuli. To study cardiac defense, this approach has developed tasks that present discrete sensory stimuli, such as noises, lights, pictures, or words, manipulating their physical features – intensity, duration, and rise time – or their affective content – pleasantness versus unpleasantness. According to this approach, cardiac defense is characterized by a heart-rate accelerative response, peaking between 3 and 6 s after the onset of stimulus, which habituates slowly with stimulus repetition.

The Motivational Approach

The motivational approach assumes that cardiac changes in response to environmental demands reflect metabolic mechanisms aimed at providing the necessary energy to the body to support behavioral adjustments (Obrist, 1981). If the appropriate behavior is to be quiet and relax, then the cardiac response will be a heart-rate deceleration. If the appropriate behavior is to be active, either physically or psychologically, then the cardiac response will be a heart-rate acceleration. To study cardiac defense, tasks have been developed that involve emotionally or cognitively challenging situations maintained throughout several minutes, such as keeping the hand in cold water, pressing a key as fast as possible to avoid shocks, or doing complex arithmetic tasks. The term 'mental stress' was introduced in this context to refer to tasks that require 'mental effort' instead of 'physical effort.' Under such conditions, cardiac defense is characterized by heart-rate acceleration maintained during the task duration, accompanied by reduced cardiac variability linked to hyperventilation and loss of respiratory sinus arrhythmia.

A New Approach to Cardiac Defense

The cognitive and motivational approaches to cardiac defense have been difficult to reconcile in the past. However, new data have been accumulated on defense responses, both in animals and humans, and on the neurophysiological brain circuits controlling such responses, which not only facilitate integration of the classical approaches but also have potential implications for the concept of stress and its relation to cardiovascular illness.

Natural Defense

In natural setting, such as the imminence of a predator, the defense reaction is not a unique response that could be conceptualized as cognitive versus motivational, or vice versa. Rather, it follows a dynamic sequential process with initial phases in which attentional factors predominate, aimed at the detection and analysis of the potential danger, and if the process continues, later phases in which behavioral factors predominate, aimed at preparation for active defense such as flight or fight. This sequential process (defense cascade) can be divided into three stages: pre-encounter, postencounter, and circa strike. Depending on the spatial and temporal proximity of the predator, different components of the defense reaction may take place successively.

Protective Reflexes

Motor startle and cardiac defense are two protective reflexes that have been extensively studied in recent years in relation to both cognitive and emotional modulatory factors (for an extensive review, see Bradley and Lang, 2007; Vila et al., 2007). Startle is a whole-body motor flexor response, which involves a quick closing of the eyes accompanied by stiffening of the head, dorsal neck, body wall, and limbs, as if to protect from a predator. It is elicited by abrupt stimulation such as a brief, intense noise or light. The response pattern habituates rapidly on repeated stimulus presentations, although some components of the reflex, such as the eyeblink, tend to persist and habituate more slowly. The startle reflex is modulated by emotional and attentional factors. The startle magnitude is augmented when the organism is in an aversive emotional state and inhibited when the organism is in a positive emotional state. Similarly, attentional factors may inhibit the startle reflex if another stimulus is presented in short proximity (prepulse inhibition) or increase it if the organism is in the attentive phase of the defense cascade.

On the other hand, studies on the cardiac components of the defense response to unexpected noises or shocks have questioned the classical models on stimulus–response characteristics, physiological mediation, and psychological significance. In the next sections, we summarize the results of a large

series of studies on cardiac defense using as basic paradigm the presentation of an unexpected intense noise under different stimulus and task conditions.

Characteristics of Cardiac Defense

Descriptive Pattern of the Response

Figure 1 represents the average second-by-second heart-rate response to an unexpected intense noise at 105 dB intensity, 500 ms duration, and instantaneous rise time. The response is represented along the 80-s poststimulus onset in terms of differential scores with respect to a baseline of 15 s prior to the stimulus. The response pattern shows two accelerative and two decelerative components in alternating order: acceleration–deceleration–acceleration–deceleration. The first acceleration/deceleration is faster, reaching its accelerative peak around second 3, whereas the second acceleration/deceleration is slower, reaching its accelerative peak around second 35. Both accelerations have larger amplitudes than the two decelerations. This response pattern can also be represented in a simplified form by selecting 10 points corresponding to the medians of 10 progressively longer intervals: two intervals of 3 s, two of 5 s, three of 7 s, and three of 13 s. This simplified representation, as shown in Figure 2, facilitates statistical analysis without altering the topographic characteristic of the response.

Stimulus Characteristics

The classical model on cardiac defense assumes that any stimulus modality sufficiently intense or aversive should be capable of eliciting the defense response. However, studies comparing four stimulus parameters – sensory modality, intensity, duration, and rise time – have found that (1) not all stimulus modalities elicit response (the auditory and electrocutaneous modalities do elicit the response pattern, but the visual modality does not); (2) stimulus intensity is an important factor increasing the amplitude of the two accelerative components (for example, a white noise at 105 dB), but the response pattern can also be elicited with auditory stimuli of moderate intensity (for example, a white noise at 79 dB); (3) stimulus duration does affect the amplitude of the first and second accelerative components: the first acceleration increases linearly as a function of duration (50–500 ms), whereas the second acceleration/deceleration is elicited only with long stimulus durations (500 ms or longer); and (4) rise time has no effect on the response pattern. The auditory modality has been the most frequently used modality to investigate the two protective reflexes mentioned above (cardiac defense and eyeblink startle). However, there are two stimulus parameters that differentiate cardiac defense and eyeblink startle with regard to their capacity to elicit the response (Ramírez et al., 2005): stimulus duration and rise time. Stimulus duration is critical to elicit cardiac defense (longer than 500 ms), whereas rise time is critical to elicit eyeblink startle (shorter than 24 ms). Thus, on manipulating these two parameters it is possible to evoke cardiac defense and eyeblink startle (intense noises of long duration and short rise time), only cardiac defense (intense noises of long duration and long rise time), or only eyeblink startle (intense noises of short duration and short rise time).

Figure 1 Cardiac defense: second-by-second heart-rate response to an unexpected intense noise. The horizontal axis represents 80 s after noise onset. The vertical axis represents the cardiac changes in beats per minute (bpm) with respect to a baseline of 15 s prior to the onset of noise.

Habituation and Dishabituation

Repetition of the acoustic stimulus results in rapid habituation of the response pattern, the second acceleration/deceleration almost disappearing after the first stimulus presentation. Although habituation is a fundamental issue in the scientific literature on cardiac reflexes (Graham, 1979), the rapid habituation of this response has been inadequately investigated. According to Graham's classical model, cardiac defense should be resistant to habituation. However, the rapid habituation of the response, especially the second acceleration/deceleration, is a consistent finding in studies where the intense noise is repeated several times with intertrial intervals (ITI) between 100 and 120 s. The first acceleration/deceleration also shows habituation, but the habituation trend is less pronounced (Ramírez et al., 2005). Two recent studies have examined the habituation and dishabituation of cardiac defense within a single session manipulating (1) the time interval between stimulus repetition (Mata et al., 2009) and (2) the acoustic quality and meaning of the stimulus (Vila et al., 2007).

In the first study, an intense white noise was presented three times by maintaining the time interval constant between the first and third presentation (30 min) and manipulating the moment of the second stimulus presentation, closer to the first one or closer to the third one. This was done in such a way as to increase and decrease symmetrically, in six-group conditions, the ITI between the three stimulus presentations. For the ITI between the first and second presentation, the time intervals were 2.5, 7.5, 12.5, 17.5, 22.5, and 27.5 min. The corresponding ITI between the second and third presentation for the same six conditions were 27.5, 22.5, 17.5, 12.5, 7.5, and 2.5 min Figure 2 presents the results for the two most extreme conditions: condition 1 (2.5 min between trial 1 and 2; and 27.5 min between trial 2 and 3) and condition 6 (27.5 min between trial

Figure 2 Habituation and dishabituation of cardiac defense: simplified heart-rate response to the three noise presentations in conditions 1 (left) and 6 (right) as a function of intertrial interval (ITI).

1 and 2; and 2.5 min between trial 2 and 3). It can be seen in Figure 2 that the expected pattern of the response, with its two accelerative/decelerative components, is observed for both conditions in the first stimulus presentation (trial 1). The expected habituation of the response – faster for the second acceleration/deceleration – is also observed in the second stimulus presentation (trial 2) when the ITI was the shortest (2.5 min). However, reduced habituation in trial 2 and increased dishabituation in trial 3 (recovery) is also observed when the ITI was the longest (27.5 min).

In the second study, a white noise and a human scream, matched in intensity and duration (95 dB and 2 s duration), were presented three times in the following sequence: 10-min rest period followed by three presentations of either the white noise or the human scream with an ITI of 120 s. Immediately after the last presentation, the same sequence was repeated with the other stimulus. As expected, the response showed rapid habituation within each sequence. However, the response pattern with its two accelerative/decelerative components was fully dishabituated (recovered) when the human scream was presented in the first sequence and the white noise in the second sequence (see Figure 3 left panel). In the opposite order, the dishabituation effect was not evident (Figure 3 right panel).

Sympathetic versus Parasympathetic Mediation

Studies examining indices of sympathetic (i.e., pre-ejection period, stroke volume, and pulse transit time) and parasympathetic (i.e., respiratory sinus arrhythmia and baroreflex sensitivity) cardiac control during the evocation of cardiac defense have found both sympathetic and parasympathetic influences (Fernández and Vila, 1989; Reyes del Paso et al., 1993, 1994). The first acceleration/deceleration is mediated by parasympathetic influences: withdrawal during the acceleration and activation during the deceleration. The second acceleration/deceleration is mediated by both sympathetic and parasympathetic influences working reciprocally: sympathetic activation/parasympathetic inhibition during the acceleration and sympathetic inhibition/parasympathetic activation during the deceleration. A coactivation of sympathetic and parasympathetic influences, with parasympathetic dominance, is also observed during the first deceleration.

Attentional versus Motivational Significance

The classical cognitive model of cardiac defense assumes an attentional interpretation of the heart-rate changes. The organism protects itself against the aversive stimulus by reducing sensory processing ('closing the sensory input'). From this cognitive perspective, defense is the opposite of orienting ('opening the sensory input'). Accordingly, cardiac defense should correlate negatively with indices of sensory intake (external attention) and positively with indices of sensory rejection (internal attention). Several studies have addressed this issue by superimposing a secondary attentional task on the evocation of cardiac defense (Pérez et al., 2000; Ramírez et al., 2010). The task could be of external attention (for example, tracking an external light on and off every half second, or performing a visual search task) or internal attention (for example, tracking one's own heartbeats or performing a memory search task). The task always started immediately after the onset of the defense stimulus. Results of these studies are very consistent confirming the opposite prediction: a positive relationship of cardiac defense with attentional processes of sensory intake (external attention).

The classical motivational model of cardiac defense assumes an energetic interpretation of the heart-rate changes. The organism protects itself by preparing for active defense

Figure 3 Dishabituation of cardiac defense: simplified heart-rate response to the human scream vs white noise when the human scream was presented in the first sequence and the white noise in the second sequence (left panel) and when the white noise was presented in the first sequence and the human scream in the second sequence (right panel).

such as fight or flight. Accordingly, the accelerative components of cardiac defense should be potentiated when participants are under negative emotional states triggered by danger or threat signals. Several studies have addressed this issue by presenting aversive pictures prior to the defense stimulus using a procedure similar to Lang's startle probe paradigm (Lang, 1995). Results of these studies are very consistent showing a marked increase in the accelerative components of the response when the emotional pictures are aversive (phobic animals or mutilated bodies). Moreover, the first deceleration disappears completely, the response being a single large acceleration finishing with the late deceleration. When the pictures were pleasant (erotic pictures) or neutral (household objects), the typical response pattern is maintained although attenuated (Sánchez et al., 2002, 2009; see Figure 4).

Figure 4 Emotional modulation of cardiac defense: simplified heart-rate response to the noise when an unpleasant, neutral, or pleasant picture preceded the noise.

Individual Differences

The data on cardiac defense reported in the previous sections are based on group averages. When the responses are analyzed on individual bases, research has consistently demonstrated important differences in the response pattern. The differences affect mainly the second acceleration/deceleration, and even absent in some individuals. Thus, a simple classification divides individuals into two categories: those showing the second acceleration/deceleration (called 'accelerators') and those not showing the second acceleration/deceleration (called 'decelerators'). However, cluster analysis has revealed four major response patterns: two patterns showing the second acceleration and two patterns not showing the second acceleration. Of the two patterns showing the second acceleration, one displays the pattern described in Figure 1, with the initial deceleration overpassing the baseline level; the other pattern does not display the initial deceleration (or the deceleration does not overpass the baseline level), the overall pattern being a single prolonged acceleration until the final deceleration or return to baseline level. Of the two patterns not showing the second acceleration, one displays a prolonged deceleration after the initial acceleration, which is maintained during the 80 s; the other pattern displays a return toward baseline after the initial acceleration. These individual differences have been found to be associated with various biological and psychological conditions, such as menstrual cycle (Vila and Beech, 1978), gender (Vila et al., 1992), personality traits (Cloete, 1979), excessive worry (Delgado et al., 2009), fear learning (López et al., 2009), and pathological anxiety (Sánchez-Navarro et al., 2012; Schalinski et al., 2013). In particular, the second acceleration has been found to be augmented in phobic women during the premenstrual phase, in men as compared to women, in people with high scores in worry and emotional instability, in people showing affective fear learning, and in patients diagnosed of some anxiety disorders. Moreover,

people with excessive worry and patients with generalized anxiety disorders or post-traumatic stress disorder tend to show the accelerative pattern without the initial deceleration, whereas people with subclinical social anxiety and patients with specific phobias tend to show the accelerative pattern with the initial deceleration, as described in Figure 1.

Dynamics of Cardiac Defense and the Brains' Defense System

The description of cardiac defense as a response pattern with both accelerative and decelerative components, parasympathetic and sympathetic influences, and attentional and motivational significance highlights the dynamic character of the defense reaction. As mentioned above, in natural settings, such as the imminence of a predator, the defense reaction is not a single response that could be conceptualized as attentional or motivational. Depending on the type and severity of the danger, its spatial proximity, the availability of a scape route, and either the success or failure in the initial responses to cope with it, different components of the defense reaction may take place successively. The complex pattern of heart-rate changes that characterizes cardiac defense, together with its complex physiological and psychological significance, can be better understood within this naturalistic perspective.

The response pattern, with its two accelerative/decelerative components, seems to reflect the succession of two defensive phases: an attentional protective phase linked to the first acceleration/deceleration, aimed at increasing attention to the potential danger, and a motivational protective phase linked to the second acceleration/deceleration, aimed at preparation for active defense. This sequential process, however, can be altered if threatening signals precede the eliciting stimulus or if the individual is already in an aversive emotional state. The data reported above on modulation of cardiac defense by aversive pictures and individual differences support this view. The change in the response pattern when phobic pictures precede the eliciting stimulus (transformed into a single large acceleration) suggests that the attentional phase has been preactivated by the aversive pictures and that the motivational phase has been advanced in time to better match successful adaptation. A similar interpretation may apply to individuals who show a single large acceleration in response to an unexpected intense noise. Such response pattern has been observed in people with high scores in excessive worry (Delgado et al., 2009) and in patients with post-traumatic stress disorder (Schalinski et al., 2013). A preexisting state of anticipatory anxiety or worry may act in the same way as the preceding aversive pictures (i.e., advancing the motivational phase).

The biological foundation of the cardiac defense response is in the brain's defensive system. What is known about this system comes from animal and human research on defensive reactions and fear conditioning (LeDoux, 1996; Lang et al., 2000). Neuroscientists have traced the chain of neural activation in the brain, starting from the sensory input, proceeding through the subcortical and cortical connecting structures, and finishing in the autonomic and motor effectors. A critical structure in this circuit is the amygdala, a subcortical center located within the temporal lobes that receives inputs from the sensory thalamus and various cortical structures, and projects on subcortical and brainstem areas that directly control specific defensive and fear reactions such as freezing (central gray), motor startle (nucleus reticularis pontis caudalis), and autonomic responses (lateral hypothalamus). This hierarchical organization of the brain's fear circuit, with common modulatory structures and different local pathways for different defense reactions, provides a considerable variety in the pattern of defensive output. Depending on the situational context and on the weight of the local pathways within the circuit, the aversively motivated responses can be freezing or escape, aggressive behavior, hormonal and autonomic responses, or the augmentation of motor startle.

Conclusion: Implications for Stress and Cardiovascular Disease

The new approach to cardiac defense has implications for the stress concept and stress-related illnesses. The classical models did not emphasize the dynamic character of the defense response or the simultaneous involvement of different physiological and psychological processes. The new model better matches the prevalent model of stress in health-related disciplines: the cognitive transactional model. The continuous dynamic interaction between the situation and the person, leading to activation or deactivation of the stress response, is the main feature of the transactional model. In addition, the new approach to defense can help to understand the specific nature of stress, differentiating it from other related concepts such as fear, anxiety, or arousal. Based on the new defense model, stress can be defined as the sustained activation of the brain's defense motivational system. A state of maintained activation of this system implies a variety of specific defense responses being continuously or intermittently elicited, including neural, endocrine, and immunological responses that correlate, in the long term, with poor cardiovascular health: maintained increases in heart rate, stroke volume, and blood pressure; and maintained decreases in respiratory sinus arrhythmia and cardiac variability. These sustained responses are instrumental for the development of cardiovascular diseases such as essential hypertension and coronary heart disease.

Stress at Work

Johannes Siegrist, University of Duesseldorf, Duesseldorf, Germany

Abstract

Stress in modern work life is subject to profound changes. This article describes these changes and identifies the role of stress at work, with emphasis on health-adverse effects. Following a definition of core terms the function of theoretical models of stressful work is explained, and major models are introduced. Research findings are summarized documenting adverse health effects. Practical implications are discussed at two levels, national labor policies and companies and their stakeholders. In addition to reducing the gap between science and policy further progress of scientific knowledge is needed, and some promising future directions are proposed.

The Changing Nature of Work and the Role of Stress

Far-reaching changes of work and employment occurred during the past few decades in economically advanced societies. Together with rapid expansion of new information technologies and automation the proportion of people working in service occupations and professions grew, and many employment arrangements became more flexible, including an increase in self-employment and informal work contracts. The current labor force of economically advanced societies is composed of a substantial proportion of women, often working in part-time arrangements, and of an increase in older workers. Although physically strenuous work and exposure to chemical, biological, and physical hazards continue to pose serious challenges to workers' health and safety, the threats of a health-adverse psychosocial work environment are now becoming more visible, and they contribute to a growing burden of work-related diseases. This latter development has been critically intensified by the recent expansion of economic globalization. Economic globalization is characterized by free market principles spreading over the world in conjunction with technological innovations, by a stimulation of large flows of transnational capital, trade, and labor force. This process is often perceived as enhancing the gross national product and as increasing the national employment rates, particularly so in rapidly developing countries, whereas its adverse consequences on the health and well-being of workers are less strongly emphasized. However, given a growing competition and pressure toward an increase in return on investment a general intensification of work has been reported as an outcome of this process (Schnall et al., 2009). In many instances, this intensification of work goes along with an increase in job instability and insecurity, due to threats of job loss or redundancy, downsizing, outsourcing, and the privatization of public services. A different consequence of economic globalization concerns the segmentation of the labor market and a related increase in income inequality. On the one hand, there is a well-trained, skilled, and flexible workforce with fair promotion prospects and adequate earnings. On the other hand, large parts of the workforce suffer from precarious employment, low wages, hazardous jobs, and low safety at work. This segmentation occurs in the context of weakened welfare state policies and reduced power of trade unions, thus augmenting the burden of stressful work among the most vulnerable and deprived groups of national workforces.

Why is work so important for human well-being, and how does work contribute to the burden of stress and its adverse effects on health? In all advanced societies work and occupation in adult life are accorded primacy for the following reasons. First, having a job is a principal prerequisite for continuous income and, thus, for independence from traditional support systems (family, community welfare, etc.). Increasingly, the level of income determines a wide range of life chances. Second, training for a job and achievement of occupational status are the most important goals of socialization. It is through education, job training, and status acquisition that personal growth and development are realized, a core social identity outside the family is acquired, and goal-directed activity in human life is shaped. Third, occupation defines an important criterion of social stratification. The amount of esteem in interpersonal life largely depends on the type of job and level of occupational achievement. Furthermore, the type and quality of occupation, and especially the degree of self-direction at work, strongly influence personal attitudes and behavioral patterns in areas that are not directly related to work, such as leisure or family life (Kohn and Schooler, 1983). Finally, occupational settings produce the most pervasive continuous demands during one's lifetime, and they absorb the largest amount of active time in adult life, thus providing a source of recurrent negative or positive emotions. It is for these reasons that stress research in organizations, where paid work takes place, is of particular relevance.

It is important to recognize that traditional occupational hazards, such as exposure to toxic substances, heat, cold, or noise, are no longer the dominant challenges of health at work in advanced societies. Although they continue to pose serious challenges, mainly to manual workers and other less qualified occupational groups, a majority of working people are now more often exposed to mental and emotional demands and threats at work. There has been a recognition that the importance of work goes beyond traditional occupational diseases and, indeed, it is likely that work makes a greater contribution to diseases not thought of as 'occupational' in conventional terms.

For instance, the organization of work plays an important role in triggering adverse health risks. This holds particularly true for shift work and long work hours. Shift work is frequent in the production sector and in some service occupations and professions. Long-standing exposure to shift work in combination with night shift increases the risk of cardiovascular disease, and a similar health risk is attributable to recurrent overtime work (e.g., working more than 50 h per week) (Härmä, 2006). In several jobs it is increasingly difficult to disentangle work obligations from private life, in particular with the expansion of electronic communication and surveillance devices. Other stressful organizational features concern overload at work, such as high demands and work pressure, frequent interruptions, or a high level of responsibility. Interpersonal conflicts at work may accelerate the burden of stressful work, in terms of lack of support and respect and unfair treatment by supervisors or coworkers. Moreover, many jobs are characterized by monotony and a low degree of skill utilization and autonomy. If combined with reduced job stability, forced part-time or downward mobility, and low wages and salaries, these challenges are likely to increase ill health at work (Schnall et al., 2009).

There is now growing awareness among all parties of the labor market that psychosocial stress at work produces considerable costs, most importantly a high level of absenteeism, reduced productivity, elevated risks of disability pensions, and direct medical expenses. However, there is a clear need to further develop scientific evidence on the links between stressful psychosocial work environments and the burden of work-related diseases. Based on improved knowledge, interventions at different levels are required to improve healthy work at large. The following paragraphs deal with these challenges in more detail.

Concepts of Work-Related Stress and Selected Findings

Research on psychosocial work-related stress differs from traditional biomedical occupational health research by the fact that stressors cannot be identified by direct physical or chemical measurements. Rather, theoretical models are needed to analyze the particular nature of the psychosocial work environment. A theoretical model is best understood as a heuristic device that selectively reduces complex reality to meaningful components. Components are meaningful to the extent that they provide the material from which the researcher can deduce explanations and, thus, produce new knowledge. Ideally, a theoretical model of psychosocial stress at work with relevance to health should encompass a wide variety of different occupations and should not be restricted to a specific time or space.

Before describing some prominent theoretical models of occupational stress, the basic terminology needs to be clarified. Much critique has been raised against the ambiguity of the term 'stress.' To avoid this, the following terms were suggested: 'stressor' is defined as an environmental demand or threat that taxes or exceeds a person's ability to meet the challenge; 'strain' is defined as the person's response to such a situation in psychological and physiological terms. Psychological responses include specific cognitions and negative emotions (e.g., anger, frustration, anxiety, and helplessness), whereas physiological responses concern the activation of the autonomic nervous system and related neurohormonal and immune reactions. Stressors, in particular novel or dangerous ones, are appraised and evaluated by the person, and as long as there is some perception of agency on the part of the exposed person efforts are mobilized to reverse the threat or to meet the demands. Such efforts are termed 'coping,' and they occur at the behavioral (even interpersonal), cognitive, affective, and motivational level. Clearly, when judging strain, the quality and intensity of a stressor as well as the duration of exposure have to be taken into account, as well as individual differences in coping and in vulnerability to strain reactions. Recent research indicates that only part of human strain reactions are subject to conscious information processing, whereas a large amount bypasses awareness. The term 'stressful experience' is introduced to delineate that part of affective processing that reaches consciousness. Stressful experiences at work are often attributed to adverse working conditions by exposed people themselves. While they usually refer to some commonsense notions of stress, it is crucial to note that these attributions differ from the explanatory constructs of stressful experience at work that have been identified by science. Next, several such explanatory constructs are described, combined with information about their empirical contribution and their practical implications. These constructs are selected from a larger number of approaches (Cartwright and Cooper, 2009) on the basis of their theoretical significance, their standardized measurement method, and the amount of empirical evidence supporting their role in explaining stress-related disorders.

Person–Environment Fit

The first significant contribution to modern occupational stress research dates back to studies conducted more than 40 years ago at the Institute for Social Research at the University of Michigan. They were guided by a theoretical concept termed 'person–environment fit' (Caplan et al., 1980). Stressful experience at work, in this model, is conceptualized in two ways: first, as an experience where the work environment does not provide adequate supplies to meet the person's needs; second, as an experience where the abilities of the person fall short of demands that are prerequisite to receiving supplies. In both conditions, stressful experience results from a misfit between needs or abilities of the working person and demands or opportunities of the work environment. Further job opportunities may fail to fulfill the person's needs as a consequence of unmet demands. As an example, a worker with limited skills is excluded from any promotion prospects, although, to meet his level of living, he badly needs better pay.

This approach represents a type of theorizing that is termed process theory. As such, it is applicable to a wide range of work situations but does not specify the particular content dimensions on which a person and environment should be examined (Edwards et al., 1998). This lack of specificity and related difficulties of measuring the model by a uniform, psychometrically validated method may explain why empirical evidence of health-adverse consequences has been relatively sparse up to now, compared to the other constructs. Nevertheless, this

pioneering approach was important in raising awareness of the combined role of situational and personal features in triggering stressful experience at work.

Demand, Control, and Resources at Work

The most extensively tested theoretical model of a health-adverse psychosocial work environment has been labeled 'demand–control' or 'job strain' model (Karasek and Theorell, 1990). Rooted in evidence from psychobiological stress research on pathological outcomes of lack of control in challenging situations (Henry and Stephens, 1977), this construct posits that strain results from job task profiles that combine high quantitative demands with lack or low degree of control. In this model, control at work is defined in two ways, as the degree of decision latitude of the working person while performing the task and as the level of skill discretion, i.e., the opportunity of using one's competencies and of learning from one's job. High-demand–low-control jobs are more prevalent among employees in lower socioeconomic positions. Therefore, they might contribute to the explanation of the social gradient of some common stress-related chronic disorders, such as coronary heart disease (CHD) and depression, leaving people in lower socioeconomic positions at higher risk (Marmot, 2004). In fact, several studies indicate that part of the social gradient of stress-related disorders is mediated by conditions measured by this construct, whereas other studies suggest that the effect of stressful work is particularly strong among workers with low social status (Siegrist et al., 2012).

Although 'job strain' can be described as a 'black box' model that does not include the person's appraisal and coping efforts at work, it nevertheless offers the advantage of being measured by job characteristics that can be objectively assessed, either by observer ratings or by classification of job titles (Karasek and Theorell, 1990). However, in the frame of epidemiological investigations, a standardized, psychometrically validated self-completed questionnaire is usually applied for economic reasons.

Based on this important, innovative model, a substantial body of research evidence was produced over the past 20 years, and several far-reaching policy implications were drawn (see below). The model was also subject to conceptual criticism, and some relevant extensions were developed. Importantly, the availability of social support at work was included in the model as a protective resource, mitigating to some extent the health-adverse effects of stressful work. Accordingly, it was found that workers confined to high-demand–low-control jobs who additionally are socially isolated on their job suffer the highest risks of stress-related disorders (Schnall et al., 2009). The notion of a fit or misfit between extrinsic demands and the working person's resources of coping with these demands has been elaborated in more recent extensions of the original model (Bakker and Demerouti, 2007), but the empirical evidence of these extensions is still limited.

Reciprocity and Fairness at Work

While the notion of personal control or autonomy in dealing with adverse circumstances in one's work and life represents a powerful psychobiological and sociological approach toward studying human health and disease (Marmot, 2004), there are additional psychosocial dimensions of work and employment that matter for health. One such dimension concerns the balance between 'give' and 'take' at work and the fairness of exchange relationships inherent in the employment contract. Scientific studies of exchange inequity (Adams, 1965) and organizational injustice (Greenberg, 2010) were developed in social and organizational psychology several decades ago, but the theoretical link of these notions with stress research, their standardized measurement, and the test of their role in explaining health-adverse effects in epidemiological and experimental studies were more recent achievements. In this context, 'effort–reward imbalance' evolved as a widely studied theoretical model of stressful work complementing the 'job strain' model (Siegrist, 1996). This model is concerned with unjust exchange at work, i.e., the lack of reciprocity between efforts spent and rewards received in return. Rewards at work include money, esteem, and career opportunities (promotion and job security). High effort in combination with low reward matters for health and well-being, as it violates a basic 'grammar' of social exchange rooted in the notions of reciprocity and fairness. High-cost–low-gain conditions at work occur frequently in modern economies. For instance, workers who have no alternative choice in the labor market, employees working in highly competitive jobs, and people with excessive work-related motivations and attitudes ('overcommitment') are particularly vulnerable to the recurrent experience of failed reciprocity at work.

The notions of personal control and social reward seem particularly relevant in explaining health-adverse effects of stressful work, partly because they address the important psychological needs of self-efficacy and positive self-esteem. Therefore, it is not surprising that the demand–control model and the effort–reward imbalance model were shown to predict stress-related disorders independently and, if experienced simultaneously, to produce additive effects on poor health (Schnall et al., 2009; Siegrist et al., 2012).

To some extent, this holds true for a related, more recently tested concept, organizational justice (Greenberg, 2010; Elovainio et al., 2002). According to this approach, adverse effects on health are triggered by the experience of perceived unfairness of distribution of valued resources, perceived unfairness of decision-making processes in organizations, and perceived unfairness of being treated by superiors and colleagues. Despite its conceptual importance, this latter approach, until now, has been less frequently tested than the two former models.

Empirical Evidence

There are three study designs that allow a test of causal associations of work stress (as measured by theoretical models as the ones described) with health. The first one is the prospective cohort study that assesses work stress (as exposure) at study entry among an otherwise healthy working population, and that follows this population over some time, identifying the incidence of a disease under study (e.g., depression or CHD), and testing the strength of association of the exposure with the risk of incident disease. The second design concerns the assessment of psychobiological or behavioral pathways that are assumed to link the exposure with the disease outcome, either by classical stress experiments or by 'naturalistic' studies of

working people's physiological activity in everyday life (e.g., ambulatory blood pressure assessment; for review Steptoe, 2006). Third, intervention studies are used to demonstrate that a reduction in exposure is followed by a subsequent reduction in disease risk.

These designs were applied with regard to established work stress models. For instance, job strain (or at least one or several components of the model) was associated with an elevated relative risk of incident CHD, ranging from about 1.3 to about 2.0. Similar results were observed for effort–reward imbalance and organizational injustice, although based on a smaller number of studies (for review Schnall et al., 2009; Siegrist et al., 2012). With respect to depression the current evidence is comparable, documenting a twofold elevated risk of incident affective disorder among those reporting high job strain or high effort–reward imbalance (Nieuwenhuijsen et al., 2010). For other stress-related disorders with relevance to occupational life, such as musculoskeletal disorders (Rugulies and Krause, 2008) or alcohol dependence (Head et al., 2004), prospective confirmation is still rare.

In addition to epidemiological information, a substantial body of research supports the notion of psychobiological and behavioral pathways linking work stress with disease. Recent studies have explored basic regulatory processes within the body, such as inflammation or cell immunity (Chandola et al., 2010), to validate the stress-physiological bases of these models. Less evidence so far is available from intervention studies, given the procedural difficulties of conducting such studies. However, a few promising results underline the importance of intervention research as further means of justifying practical consequences derived from scientific findings (Schnall et al., 2009).

In summary, despite some inconsistencies and methodological challenges, a robust body of scientific evidence is now available demonstrating associations of an adverse psychosocial work environment, as assessed by established theoretical models, with a range of stress-related disorders.

Practical Implications and Future Directions

Unhealthy work produces substantial economic costs and reduces the health, well-being, and work performance of a large proportion of the workforce. It is therefore disappointing to observe that investments into good quality of work and employment are still relatively modest, at least in an international perspective. In addition to scientific evidence there are now several models of good practice available that demonstrate how successful solutions can be implemented at different levels. One level concerns national labor and social policies that contribute to a reduction in the burden of stressful work, e.g., by protecting workers from job instability and redundancy; by controlling overtime work, shift work, and exposure to occupational hazards; and by providing comprehensive occupational health and safety services that also meet prevention and rehabilitation needs of occupational risk groups. To this end, it is important to implement reliable and valid monitoring and surveillance systems to assess the burden of work-related stress and to guide preventive activities. Several pioneering examples are available from European countries, such as Denmark or England (Siegrist et al., 2012).

A second level addresses single companies, organizations, and stakeholders. Here, knowledge derived from theoretical models of stressful work can be used to promote employees' health. As stated above, person–environment fit theory concludes that work demands need to be tailored according to the worker's abilities. This involves both specific measures of organizational development and individual skill training. In the demand–control model, special emphasis is put on autonomy, skill discretion, and personal growth. Measures of work reorganization include job enlargement, job enrichment, skill training, enhanced participation, and teamwork. Practical implications of the effort–reward imbalance model concern the development of compensatory wage systems, the provision of models of gain sharing, and the strengthening of nonmonetary gratifications, including leadership behavior. Fair promotion prospects and procedures, and the development of a culture of trust, transparency, and sustainability, are additional measures derived from this model as well as from the organizational justice model. Importantly, these practical applications are not restricted to primary prevention but are equally valid for secondary prevention, aiming at an improvement of return to work among chronically ill, disabled, or unemployed people (Schnall et al., 2009; Siegrist et al., 2012).

To summarize, the quality of work is an important determinant of health and well-being. Recent scientific progress has identified promising entry points of interventions at the macro-, meso-, and microstructural level of policy measures. Thus, a major effort should be directed toward reducing the gap between available scientific knowledge and the implementation of policies that contribute to improved health at work. An additional effort concerns the achievement of further scientific progress.

Future Challenges for Research

There are several promising directions of future occupational stress research. First, although we witness a rapid growth of empirical evidence in the frame of epidemiological and experimental investigations, there is still a substantial lack of theory-based intervention studies demonstrating beneficial long-term effects of structural and/or behavioral changes at work. Many studies address the individual or interpersonal level rather than measures of organizational change. Positive findings are often derived from relatively privileged groups of employees, less so from low-skilled groups who suffer most from adverse employment and working conditions. In this area of research, far-reaching methodological challenges prevail as it proves to be difficult to conduct randomized controlled trials, the gold standard of evidence-based medicine. Eventually, interventions are compromised by unanticipated business changes, and control groups may be exposed to some extrinsic developments with beneficial effects. Thus, the advancement of appropriate methodological approaches seems to be a topic of high priority.

A second direction of research addresses the link or interface between work and nonwork settings, in particular work and family ('work–life balance'). In advanced societies, work and family have been identified as the two most central domains, especially so in midlife. Therefore, stress-enhancing and stress-buffering experiences in these two domains significantly contribute to personal health and well-being. This interface is

conceptualized in terms of spillover, compensation, or cumulation. Spillover refers to the transfer of experience and behavior from one domain to the other. For instance, work overload or shift work schedules may have negative effects on family life. Alternatively, experience of competence and success at work can have beneficial effects on marital life and relationships between parents and children (Kohn and Schooler, 1983). Compensation represents efforts to reduce stressful experience in one domain by improving satisfaction in another domain. For instance, leisure and family activities are enhanced to the extent that decreasing involvement in a stressful work environment is feasible. Compensation often occurs in terms of resource management in a stressful situation. In conceptual terms, there is some overlap between the buffering model of social support and compensation processes. Cumulation refers to the fact that the critical components of stressful psychosocial experience, such as lack of control or effort–reward imbalance, generalize across core life domains. For instance, disease vulnerability may be the highest among people with insecure, badly paid, effortful jobs who also live in a family arrangement that offers little emotional and material satisfaction. It is desirable to extend the theoretical models discussed, both conceptually and operationally, to life domains other than work.

Third, given the challenges of a globalized economy, the advances of work stress research that were mainly achieved in countries with modern economies need to be transferred to rapidly developing countries. In this bidirectional process of exchange, theoretical and methodological extensions and adaptations may enrich the field of research, given the powerful diversity of cultural traditions and socioeconomic developments. However, it is equally important to generate robust knowledge about those unhealthy work and employment conditions that produce similar adverse effects in different countries and branches across continents. It is only at the level of international organizations and concerted political actions that such global trends can be tackled. In conclusion, in view of the importance of work for health, it is well justified to advance the field of occupational stress both at the science and policy level.

Abstract

Stress has been consistently associated with negative health outcomes, including increased rates of heart disease, slower wound healing, and compromised immune function. Interventions designed to improve peoples' ability to cope with stress can improve health outcomes. Such interventions include relaxation training, emotional expression, benefit finding, and cognitive-behavioral stress management and mindfulness-based stress reduction programs. Coping interventions have the potential to improve health outcomes for patients undergoing a stressful illness experience.

Introduction

There is a large body of literature surrounding the impact of stress on health, and more recently on how coping effectively with stress might influence this relationship. Most people are able to identify a stressful event or experience when it is happening to them. However, attempting to provide a definition of 'stress' that accurately encompasses the vast range of experiences that people might report as stressful elucidates stress as a broad and subjective concept.

Within the social and behavioral sciences, much of the literature on stress stems from the work of Lazarus and Folkman (1984). Their model views stress as occurring when an individual is faced with a situation that places demands on them, but for which the individual does not have the necessary resources to manage these demands. Importantly, this situation must be appraised as personally relevant to the individual, making stress a transactional process between the person and their environment. Segerstrom and O'Connor (2012) highlight that 'stress' can originate from a variety of sources, including from the environment, personal appraisal, and response to a situation.

Stress and coping are difficult to disentangle, and it is hard to imagine the need to attempt to cope without being first faced with a stressor of some sort. Indeed, coping is often viewed as an attempt to deal with a demanding situation in a way that removes the threat or at least minimizes its impact on the individual (Carver, 2006). These attempts may involve the use of cognitive and behavioral strategies in order to manage the stressful situation (Folkman and Moskowitz, 2004).

Lazarus and Folkman (1984) proposed different broad types of coping. Problem-focused coping is aimed at the source of the stress, and involves attempts to remove or avoid the threat itself. For example, a person who feels that they are at high risk of developing cancer may engage in problem-focused coping by quitting smoking, changing their diet, or taking part in an exercise program. Emotion-focused coping is aimed at managing the emotions associated with stressful experiences. In the example above, the same person may engage in emotion-focused coping by adjusting their personal perception of risk, or reframing the threat; 'we all have to die of something.' Importantly, while coping is typically thought of as a positive process, this is not necessarily the case. Likewise, it cannot be assumed that coping strategies that are adopted will necessarily be appropriate or effective in helping an individual avoid or reduce the impact of a stressor (Carver, 2006).

The focus of this article is on the relationship between stress, coping, and physical health. Health in this context is seen as the presence or absence of disease states, physiological markers of underlying disease processes, rates of healing from physical injury, and the functioning of the immune system.

Stress and Health

There is evidence spanning many fields of scientific enquiry that links stress and health. While the mechanisms may not be fully understood at this stage, it is clear that experiencing an event or situation that is perceived as stressful can have negative consequences for physical health. While the majority of evidence points to the negative impact of stress on health outcomes, it is worth noting that in some cases stress can have a beneficial impact; for example, in encouraging people to more rapidly seek assessment of worrying physical symptoms (Meechan et al., 2003).

Disease Outcomes

Perhaps one of the largest literature linking stress to disease outcomes involves cardiovascular disease. The experience of a relatively brief stressor has been associated with increased risk of experiencing a cardiac event. For example, the death of a loved one substantially increases the risk of a cardiac event in the month following the loss (Kaprio et al., 1987). Other acute stressors, including natural disasters, missile attacks, or even watching a tense sports contest have also been associated with increased mortality from heart attacks (Leor et al., 1996; Meisel et al., 1991; Wilbert-Lampen et al., 2008).

Chronic or ongoing stress has also been reliably associated with increased cardiac morbidity. Greater exposure to chronic work stress has been linked to higher blood pressure (Schnall et al., 1998) and a greater risk of coronary heart disease (Steptoe and Kivimaki, 2013). Actual and remembered hostile marital interactions can increase blood pressure (Carels et al., 1998; Ewart et al., 1991), and women with coronary heart disease who experience chronic marital stress are almost three

times more likely to experience recurrent cardiac events (Orth-Gomér et al., 2000). The chronic stress of social isolation also confers an increased risk of coronary heart disease (Steptoe and Kivimaki, 2013). A recent review of the role of stress in cardiovascular disease highlights the impact that stress can have across decades; stressors experienced during childhood, including abuse and socioeconomic adversity, are associated with higher rates of later cardiovascular disease in adulthood (Steptoe and Kivimaki, 2013).

There is also evidence for the role of stress in other disease processes. Reported physical illness increased 18% in the 3 years following the terror attacks of 9/11 in the United States (Holman and Silver, 2011). In a group of men undergoing prostate-specific antigen level testing, higher levels of distress at initial testing was associated with a 23% increased risk of receiving a prostate cancer diagnosis (Turner et al., 2009). Psychological distress has also been associated with more rapid HIV disease progression and associated $CD4^{+}$ T cell decline (Yoichi and Vedhara, 2009).

Wound Healing

Another body of work focuses on the relationship between the experience of stress and the rate with which wounds heal over time. A recent review and meta-analysis demonstrated a robust relationship between stress and wound healing, with higher levels of stress being associated with slower healing rates or other physiological markers of impaired healing (Walburn et al., 2009). These findings were seen in naturally occurring and experimental wounds, acute and chronic wounds, using different definitions and assessments of stress.

Much early work in this area has focused on standardized wounds created for the purposes of research. When comparing wound healing rates in women who were caregivers for a family member with Alzheimer's disease to matched controls, Kiecolt-Glaser and colleagues found that the experimentally inflicted wounds took a significantly longer time to heal in caregivers compared to the control participants (Kiecolt-Glaser et al., 1995). Similar findings were seen when comparing students across examination and vacation time periods; punch biopsy wounds took approximately 40% longer to heal during the stressful examination period (Marucha et al., 1998).

The impact of stress on wound healing is also seen in wounds created through surgical intervention. In patients undergoing hernia surgery, those with greater reported preoperative stress levels demonstrated an impaired immune response following surgery, as well as experiencing a more painful and slower recovery (Broadbent et al., 2003).

Immune Function

Wound healing appears to be mediated by a more adaptive immune response following tissue injury. Immune activity and the impact of stress can also be assessed using other measures of immune function, including susceptibility to viral infection and immune response to vaccination. When exposing healthy participants to the common cold virus, those with higher reported stress levels were more susceptible to infection than their less stressed counterparts (Cohen et al., 1991). Similarly, when comparing elderly participants who were caring for a spouse with dementia to control participants, caregivers produced fewer antibodies in response to a pneumococcal bacterial vaccination both 3 and 6 months after immunization (Glaser et al., 2000). However, when looking at a younger sample of spousal caregivers, similar declines in immune function have not been seen (Vedhara et al., 2002).

The effects of stress on infection appear to be seen predominantly in response to chronic stressors, which are associated with an increased risk of infection with a cold virus; however, more acute stress lasting less than 1 month was not (Cohen et al., 1998). Indeed, there is some evidence that acute stress can result in an enhanced immune response, as evidenced by higher antibody titers following vaccination (Edwards et al., 2006). A recent meta-analysis supports this and indicates that brief or acute stress may result in increased activity of natural immunity including natural killer cells and large granular lymphocytes, although acute stress does not appear to be beneficial in all instances or across all immune parameters (Segerstrom and Miller, 2004).

Coping and Health

A large body of work has sought to understand what coping strategies are associated with better health outcomes. Additionally, recent research has focused on developing coping interventions with the aim of improving patient outcomes. Peoples' coping reactions to a stressful event can vary markedly. Carver and colleagues investigated the effects of different coping strategies in a group of women undergoing treatment for early stage breast cancer (Carver et al., 1993). Lower levels of distress both before and after surgery were seen in women who reported using the coping strategies of acceptance, positive reframing, and humor. Denial and behavioral disengagement were associated with greater distress. All the women in the study were experiencing a similar stressor, yet their coping strategies and resultant distress levels varied widely.

A review of the coping literature notes that coping is associated with regulating emotions; while our focus tends to be on negative emotions and distress, positive emotions also occur alongside negative emotions, which can lead to health benefits (Folkman and Moskowitz, 2004). Importantly, the authors also note that coping skills can be taught. It is this process, and the utility of coping interventions in improving health outcomes, that will be the focus of this section. A recent review by Broadbent and Koschwanez (2012) highlights recent advances in wound healing and psychological interventions in clinical populations.

Relaxation Training

Relaxation training aims to reduce stress by lowering levels of physiological arousal, and it is included in many stress management interventions (Taylor, 2012). The effectiveness of relaxation training has been investigated as a possible intervention for improving markers of wound healing following surgery (Broadbent et al., 2012). Patients undergoing

laparoscopic cholecystectomy were randomly assigned to receive a guided imagery and relaxation intervention or standard care. Participants who received the intervention reported reduced perceived stress and increased hydroxyproline deposition, a marker of collagen deposition and healing, in the surgical wound. However, the mechanism of action remains unclear, as changes in perceived stress were not associated with rates of wound healing.

Emotional Expression

Another coping strategy that has been examined as an intervention in the context of health is that of emotional expression. It is thought that inhibiting negative emotions takes physiological effort, thus greater inhibition must be facilitated by increased physiological activity (Pennebaker, 1997). The physiological effort necessary for such inhibition may result in fewer resources being available to support other important bodily processes. Being asked to suppress thoughts, whether they are related to trauma or more mundane events, can result in a reduction in circulating immune cells, including T lymphocytes (Petrie et al., 1998). The ability to express or disclose negative emotions may reduce the need for such inhibition, reducing physiological demand (Stanton, 2010). Written emotional disclosure has the ability to increase reported physical health as well as physiological functioning in healthy participants (Smyth, 1998).

Emotional expression does not appear to be beneficial for all people or across all stressors (Stanton and Low, 2012). Expressing emotions appears to be of greatest utility for helping people adjust in situations in which they have low levels of control, where emotion-focused coping strategies tend to be of greatest benefit. Additionally, emotional expression seems to be of most benefit to people who already have a tendency toward emotional expression before encountering a stressor, and who experience intense emotions. Finally, the benefit of disclosure depends on the reactions of those to whom people choose to express their emotions. Written disclosure of a secret while imagining an accepting response from another person results in fewer reported illnesses following the experiment compared to a group imaging a nonaccepting response (Rodriguez and Kelly, 2006).

Stanton and colleagues investigated the coping strategies of women with stage I or II breast cancer, and found that women who expressed their emotions about cancer had better psychological and physical outcomes following medical treatment, including less distress, fewer cancer-related medical appointments, and enhanced physical health (Stanton et al., 2000).

Early experimental work in this area found that writing about traumatic events once a day for 4 days resulted in higher blood pressure and more negative mood immediately after writing. However, the students who were randomly assigned to write about a trauma visited the student health center fewer times during the 6 months following the writing task than those who wrote about trivial events (Pennebaker and Beall, 1986). Similarly, medical students who were randomly assigned to write about traumatic events had higher antibody levels following a Hepatitis B vaccination compared to control participants (Petrie et al., 1995). Wound healing is also enhanced in older adults engaging in expressive writing compared to control participants (Koschwanez et al., 2013).

Expressive writing also appears to confer some benefits to patient populations, and such interventions appear to have a high degree of acceptability. In HIV patients, writing about emotional topics was associated with increased CD4+ lymphocyte counts following the intervention compared to participants writing about control topics (Petrie et al., 2004). Breast and prostate cancer patients have been shown to experience a reduction in physical symptoms and less medical care utilization following writing interventions; however, the mechanism is unclear, as levels of emotional distress do not appear to be affected by the expressive writing tasks (Corter and Petrie, 2011).

Mindfulness-Based Stress Reduction

Mindfulness-based stress reduction (MBSR) involves using meditation training to help people develop skills to enable them to regulate their emotional reaction to stress (Brown and Ryan, 2003). MBSR does appear to be an effective intervention in improving coping and health across a wide range of conditions, including various cancers, coronary artery disease, and fibromyalgia (Grossman et al., 2004). In women who were recently diagnosed with early stage breast cancer, an MBSR intervention resulted in increased natural killer cell activity and cytokine production, as well as increased coping effectiveness compared to the control group (Witek-Janusek et al., 2008). A recent trial found that patients with irritable bowel syndrome who received MBSR training experienced significant improvement in symptom severity compared to a wait-list control group (Zernicke et al., 2013). However, MBSR training was not found to be effective in reducing ambulatory blood pressure in patients with hypertension when compared to wait-list controls (Blom et al., 2014).

Cognitive-Behavioral Stress Management

Cognitive-behavioral stress management (CBSM) interventions are composed of training in techniques including relaxation, cognitive restructuring, social skills, and recognizing environmental stressors (Lichstein, 1988). Following a CBSM intervention, elderly spouses caring for dementia patients demonstrated an improved immune response to an influenza vaccination when compared to both nonintervention caregivers and noncaregiver control participants (Vedhara et al., 2003). Improvements in immune function, including increased cytokine production and reduced cortisol, have also been found in postsurgical breast cancer patients who have undergone a CBSM intervention when compared to control patients (Antoni et al., 2008).

In a recent study, Antoni et al. (2012) found that a CBSM program for women with breast cancer reversed leukocyte gene expression, downregulating proinflammatory and metastasis-related genes. This suggests that stress management interventions may impact directly on immune activity by influencing proinflammatory processes at the level of gene expression. There also is some evidence to suggest that the effectiveness of CBSM may be mediated by increased benefit finding (Cruess et al., 2000).

Benefit Finding

Benefit finding is a commonly utilized emotion-focused coping strategy; many patients identify positive effects that follow a serious illness. In a group of heart attack and breast cancer patients, almost two-thirds reported some positive changes following their illness; myocardial infarction patients most often reported a healthy lifestyle change, while a closer relationship with others was the most common theme reported by breast cancer patients (Petrie et al., 1999). An experimental written emotional disclosure study with breast cancer patients found that participants who were encouraged to write about positive aspects of their breast cancer experience required fewer cancer-related medical appointments in the 3 months following the intervention compared to control participants (Stanton et al., 2002).

Conclusions

Stress is a transactional process involving an individual and their environment. Situations that place demands on a person that they do not see themselves as having the resources to meet are typically experienced as stressful. However, there is much variation regarding what situations will generate such a response between individuals and even within the same person on different occasions.

Research into the impact of stress on health involves both specific experiences that are likely to be stressful, as well as more general personal perceptions of stress. Acute stressors discussed in this article include the death of a loved one, environmental disasters, and examination stress. Chronic stressors that have been investigated include marital discord, being a caregiver for an ill spouse, and workplace stress. Importantly, the experience of a serious illness is also often perceived as a highly stressful event. Across a broad range of stressors, it is clear that stress can have negative consequences for physical health. Such consequences include increased rates of cardiovascular disease, slower healing of both experimental and surgical wounds, and dysregulation of immune function.

While stress can be detrimental to health, it is worth noting that, under some circumstances, the experience of stress can also prove to be beneficial. The stress process involves the experience of both negative and positive emotions, and these positive emotions can result in health benefits. There is also some evidence that certain acute stressors can enhance the functioning of some aspects of the immune system. Finally, the experience of distress following the discovery of physical symptoms is associated with more rapid health care seeking, enabling prompt access to treatment should it be needed.

While the experience of stress tends to be associated with negative health outcomes, coping provides a potential pathway by which to mitigate this damage. Coping refers to attempts to remove or reduce the threat that a stressful situation presents. Such attempts may involve cognitive or behavioral strategies, directed at the problem itself, or at managing negative emotions associated with the stressful experience.

However, the coping strategies that people engage in may not necessarily be helpful or successful in reducing stress or eliminating a threat. This highlights the importance of interventions that are aimed at teaching adaptive coping strategies that can improve health outcomes. Research has investigated a number of coping interventions, including relaxation training, emotional expression, benefit finding, and MBSR and CBSM programs. All of these have been associated with improved health outcomes.

It is likely that these interventions will have the most benefit when they are appropriately matched to both the individual and the situation. Participants with a natural tendency for emotional expression are likely to benefit more from such interventions, and emotion-focused techniques appear to be more useful in situations where participants have low levels of control over the stressful situation.

The mechanisms by which such interventions work require more investigation. Some studies report better health outcomes in the intervention group, but do not demonstrate a reduction in perceived stress, although it is possible that physiological changes may precede psychological adaptation. Regardless, the strong evidence linking high levels of stress to worse health outcomes and the promising results from a number of coping studies, suggest that with appropriate interventions health outcomes for many patients could be improved.

Stress: Effects on Neonatal and Child Development

Abstract

If a mother is stressed, anxious, or depressed while pregnant, her child is at greater risk of a range of problems, including increased anxiety, attention deficit hyperactivity disorder, and conduct disorder, as well as lower birthweight. The mechanisms underlying this fetal programming are starting to be understood and probably involve altered placental function. There may be an evolutionary value in the changes observed, which helped the child to survive in a stressful environment in early human communities, but are maladaptive now. The clinical implications are that better emotional care of pregnant women should help to improve the outcomes for their children.

Introduction

If we want to understand the child development, or the origins of psychopathology, we need to start before birth. It has been known for many decades that how we turn out depends on an interaction between our genes and our environment. What we now realize is that an important part of our environment is in the womb. This is because of fetal programming, the fact that the milieu in the womb, during different sensitive periods for specific outcomes, can alter the development of the fetus, with a permanent effect on the child and later adult. David Barker has conducted epidemiological studies, which have now been confirmed by many independent groups across the world, that show that a healthy lower birthweight baby is at greater risk of dying from cardiovascular disease in later life, than a larger newborn baby (Barker, 2007). If organs such as the kidney or the pancreas develop less well in the womb they may cope less well with an adverse environment later.

There is now considerable evidence that fetal programming is also important for neurodevelopment and that the mother's emotional state during pregnancy can affect the development of her baby's brain (Van den Bergh et al., 2005; Talge et al., 2007; Charil et al., 2010). This has been known for many decades from animal studies (Weinstock, 2001). It has been shown that in rats, guinea pigs, and monkeys, if the pregnant animal is stressed there are long-term effects on the offspring. These include increased anxiety, reduced attention, and many structural and functional changes in the brain. In animal studies, the effects can be proved to be prenatal rather than postnatal because the offspring can be crossed fostered to a mother not stressed during pregnancy, or in the case of monkeys, all the offspring can be reared together in a nursery.

Longitudinal Human Studies – Types of Outcomes Affected

The risk for a wide range of different outcomes has been shown to be raised in humans in association with prenatal stress (see Table 1). These include both neurodevelopmental, such as emotional and behavioral problems, and physical problems, such as asthma. It is important to note that in all these studies, the findings show only an increased risk. Most children are not affected. But an increased risk, for example, a doubling of emotional/behavioral problems from 5% to 10%, if the mother is in the top 15% of anxiety or depression as shown in a normal population (O'Connor et al., 2002), is of real clinical significance.

Different studies have examined children at times from birth until adulthood. Many have shown that prenatal stress is associated with somewhat lower birthweight and reduced gestational age. Another finding at birth is an altered sex ratio, with fewer males to females being born than in an unstressed population. Studies have found an increased proportion of children who are mixed handed, rather than right handed, after prenatal stress, and also altered fingerprint patterns. These physical alterations are of interest because they are features that are known to develop *in utero*. Being mixed handed is not a problem in itself, but it is known that people with a range of neurodevelopmental problems such as autism and schizophrenia are also more likely to be mixed handed. A recent study has shown that prenatal stress is associated with reduced telomere length. Telomeres are the end pieces of DNA on each chromosome, which protect them from deterioration. This is an intriguing finding, as well as of concern, as reduced telomere length is associated with a reduced life span.

Table 1 Neurodevelopmental and physical outcomes shown to be associated with prenatal stress

Neurodevelopmental outcomes	*Physical outcomes*
Altered neonatal behavior	Reduced birthweight
More difficult infant temperament	Reduced gestational age
Altered sleep pattern in infants	More mixed handedness
	Altered sex ratio; fewer boys born
Increased anxiety and depression in children	Altered fingerprint pattern
Increased behavioral problems: ADHD, conduct disorder in children	Decreased telomere length
Impaired cognitive development, especially language in children	Increased asthma
Increased autism in children?	Reduced immune function
Increased schizophrenia in adults	Increased obesity
	Increased diabetes

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23003-1

Some investigators have looked at the newborns of mothers who report stress during pregnancy and found a poorer performance on the Neonatal Behavioral Assessment Scale relative to newborns of mothers who do not report stress during pregnancy, showing that adverse behavioral outcomes are also observable from the very beginning. Studies of infants and toddlers have shown more difficult temperament, sleep problems, lower cognitive performance, and increased fearfulness associated with higher maternal stress during pregnancy. Other studies have examined the association between prenatal stress and neurodevelopmental outcomes in children aged 3–16 years. Many independent groups have shown that prenatal stress increases child emotional problems, especially anxiety and depression, and symptoms of attention deficit hyperactivity disorder (ADHD) and conduct disorder. Other studies have shown a reduction in cognitive performance associated with prenatal stress.

Some research has found an association between prenatal stress and increased risk of autism, although a large population study has failed to confirm this. Two studies have found an increased risk of schizophrenia in adults born to mothers who experienced stress during pregnancy. Both showed effects with severe stress, the death of a relative or exposure to the invasion of the Netherlands in 1940, and both showed that the sensitive period of exposure was during the first trimester. One group, using magnetic resonance imaging, has shown associations between prenatal stress and specific regional reductions in gray matter density in the brain. Such altered gray matter may be associated with neurodevelopmental and psychiatric disorders as well as cognitive and intellectual impairment.

There is little consistency in the literature as to the most sensitive time in gestation for the influence of prenatal stress. It is likely that there are different times of sensitivity dependent on the outcome studied and the stage of development of the relevant brain structures. The two studies of schizophrenia found that the most sensitive period was in the first trimester. This is when neuronal cells are migrating to their eventual site in the brain, a process previously suggested to be disrupted in schizophrenia. In contrast, two studies of conduct disorder, or antisocial behavior, found the greatest associations with stress in late pregnancy.

Types of Prenatal Stress Associated with Altered Child Outcome

Stress is a generic term, which includes a wide range of different types of exposure, and many have been shown to be associated with altered outcome for the child. They include maternal anxiety and depression, pregnancy-specific anxiety, daily hassles, bereavement, life events, a bad relationship with the partner, and exposure to acute disasters such as a Canadian ice storm, 9/11, Chernobyl, a hurricane in Louisiana, or war. It is clear that it is not just a diagnosable mental illness or very extreme or 'toxic stress' that can alter outcome. Exposures that can have an effect vary from the very severe, such as the death of an older child to quite mild stresses, such as daily hassles.

It has been suggested that mild to moderate stress may actually improve some outcomes. Mild prenatal stress has been shown in some studies to accelerate motor development and cognitive ability. This is an interesting idea and deserves further investigation. Other studies have found a linear dose response between prenatal maternal anxiety and emotional/behavioral outcomes for the child. It is possible that prenatal stress has different patterns and direction of effect for different outcomes. For example, mild to moderate stress may accelerate physical maturation and cognitive function while also increasing symptoms of anxiety.

Is It Causal?

Many human studies, as discussed earlier, have shown that there is an association between maternal stress during pregnancy and an altered outcome for the child. The evidence for this is very strong and has been shown in many independent prospective studies from around the world. What is harder to establish is that the association is causal. If a mother is stressed while she is pregnant she may well be stressed postnatally and this could affect her parenting. There can be other associated confounding factors such as smoking or alcohol consumption, which may affect her child, for example, in behavior and birthweight. There also could be genetic continuity. The mother may have certain genes which make her more likely to become anxious or depressed and she may pass these genes on to her child, which in turn makes them more prone to emotional or behavioral problems.

Several studies have tried to address these points but the first evidence to consider is that from animals. With animal studies it is much easier to establish that prenatal stress has a direct effect on the outcome for the offspring. Newborn rat pups of prenatally stressed mothers can be cross fostered to nonstressed mothers on the first day after birth, with control pups of unstressed mothers cross fostered also. This can establish that any differences in outcome are caused by stress in the prenatal period. Many such studies have shown that there are definite programming effects of prenatal stress on behavior, cognitive development, and brain structure of the offspring. The nature of the effects can be affected by the timing of the exposure in gestation, the type of the stress, the strain of the animal, the age at which the offspring was tested, and the sex of the offspring. Some altered outcomes are not observed in the youngest offspring, but become apparent as they mature. The effects can also depend on the sex of the offspring. In general, although not always, prenatal stress increases anxiety and depressive behavior to a greater extent in female offspring and impairs learning and cognition more in the males (Weinstock, 2007).

In the animal studies, there has been much research on the underlying mechanisms. The effects of prenatal stress on the offspring can often be mimicked by giving the stress hormone cortisol (corticosterone in rodents), or a synthetic glucocorticoid such as dexamethasone, to the pregnant animal. Some of the effects of prenatal stress can also be moderated by the quality of the postnatal maternal care. All is not over at birth.

In humans there are several types of evidence which also suggest that prenatal stress is causing fetal programming, but it is harder to be definitive. There is good evidence for an association between the mother's emotional state and the behavior or heart rate of her fetus. Experiments in which a pregnant mother is asked to carry out a stressful computer task, while the

fetal heart rate is monitored, showed that the fetal heart rate went up during the task, but only in mothers who rated themselves as anxious. Thus even before birth the fetus can be affected by the maternal emotional state, although we do not know what the mechanism is for this are (it is too quick to be caused by the stress hormone cortisol). There is evidence for continuity between fetal behavior and neurological maturation in the first weeks after birth. The fact that maternal stress during pregnancy is associated with altered outcomes at birth including reduced birthweight and reduced scores on a neonatal assessment is some evidence for prenatal, independent of postnatal, effects.

Another approach to establishing that the associations between the maternal emotional state and long-term outcome for the child are, at least in part, causal, is by controlling for confounding factors such as prenatal smoking and alcohol consumption, and for postnatal maternal mood. Several studies have done this and found a strong signal remaining for prenatal anxiety or depression, thus controlling for impaired parenting due to postnatal depression or anxiety (O'Connor et al., 2002). If the observed associations are primarily due to an anxious mother passing on predisposing genes to her child, it would not be expected to be specifically associated with prenatal as opposed to postnatal mood. There clearly are additional effects of both postnatal maternal mood and parenting. For example, the association between prenatal anxiety and child fearfulness was found to be greater in those children with an insecure attachment to their mother. However, many studies have shown that there is good evidence for a prenatal causal component also.

An interesting study compared the association between prenatal stress and child outcome, in children born after *in vitro* fertilization, in those who were genetically related to the mother with those who were not (Rice et al., 2010). They showed that there was an association between maternal stress in pregnancy and child symptoms of ADHD and conduct disorder, and that the association with conduct disorder was apparent in the unrelated mothers. This gives strong support to the idea that the association between prenatal stress and child conduct disorder is independent of genetic factors. However, the fact that the increase in symptoms of ADHD was apparent only in those with related mothers does not conclusively rule out a prenatal environmental component. There may be a gene–environment interaction. Prenatal stress may only have the effect of increasing symptoms of ADHD in the genetically vulnerable mother and child pairs. More research is needed to disentangle the role of genetic factors for all outcomes.

One further indication that the effects of prenatal stress are not just due to genetic continuity is the group of studies that have shown children of mothers exposed to acute disasters, such as the Canadian ice storm (Laplante et al., 2008). With these 'natural experiments,' the level of stress was objectively assessed, and the exposure was of a specific duration. This reduces the confounding effects of pre-existing emotional problems and genetic continuity, and also postnatal emotional and parenting effects.

Although there is some room for skepticism, the evidence is mounting that in humans, as in animals, prenatal stress has a direct causal effect on fetal development including neurodevelopment. However, the early postnatal environment is equally important and can either exacerbate or ameliorate the prenatal effects.

Evolutionary Significance

The changes that we observe in the child whose mother was exposed to stress during pregnancy may be explained in evolutionary terms. Maternal prenatal stress and anxiety may program the offspring to respond more effectively in a future dangerous or stressful environment (Glover, 2011). The programming effects do not seem to be specifically associated with a particular clinical diagnosis in the mother, as discussed earlier, but with a range of different conditions which make her feel stressed. Our emotions and behaviors have been shaped by natural selection. Attacks by predators, exclusion from the group, and opportunities for mating were sufficiently important and frequent to have shaped special patterns of behavior. Some of the altered outcomes observed after prenatal stress, may well, in their milder forms, have also been adaptive for our ancestors. But a mismatch between what was adaptive in an earlier environment and the world in which we now live, can lead to pathology. Mammals have developed the capacity to respond in an appropriate way *in utero*, presumably to improve fitness, and be better prepared for the environment in which they would find themselves after birth (Gluckman et al., 2005).

It is of interest to speculate how the various changes observed in children exposed to prenatal stress may have been adaptive in a stressful environment for early human communities. One of the most common findings in children who have been exposed to prenatal stress is an increase in anxiety. Normal anxiety is an emotion that helps organisms defend against a wide variety of threats. This evolutionary perspective on anxiety explains why we are more likely to develop phobias to archaic dangers like snakes or spiders, and not to modern dangers, such as cars. It is easy to see how extra vigilance may be more necessary and adaptive in a more stressful environment. A mild threat causes a general increase in anxiety that helps to locate the source and type of danger and to plan possible ways to deal with it.

Another common outcome associated with prenatal stress is ADHD. Distracted attention may be adaptive in a dangerous environment, which the pregnant mother has experienced as stressful. Sensitivity to small signals, such as a new sound, may alert one to the approaching presence of a predator or a hostile human. The hyperactive/impulsive dimension of ADHD, novelty seeking, risk taking and seeking maternal attention as well as increased sexual activity, all may have been adaptive too. Novelty seeking and increased exploration could propel migration, which could be important in a stressful environment. Exploration does not always have to be well organized. Random search strategies can be beneficial too.

An increased risk of conduct disorder is also associated with prenatal stress. It is easy to understand how more aggressive behavior may be adaptive in a stressful environment in which there is a shortage of resources or more danger from outsiders. Our early human ancestors could have been at risk from carnivorous predators and also from other humans, such as

neighboring tribes. An ability to react quickly, and to be aggressive, as well as to mount stress responses, may have been helpful to escape or to fight back. Other aspects of conduct disorder may be adaptive in such circumstances too. For example, breaking the rules, or behaving in a way different from the group, may aid the discovery of new environments or new strategies. In times of stress or difficulty, those with these dispositions may be the ones who try out new things or literally explore new areas.

We do not know to what extent the cognitive impairment detected after prenatal stress is a side effect of readily distracted attention or other behavioral changes. However, there may be advantages in having cognitive variation in a population, similar to the possible benefits of impulsivity. Individuals who learn, understand, and interpret things in different ways may also have had adaptive advantage under varying conditions in an earlier society.

Underlying Biological Mechanisms

Little is understood about the mechanisms that may underlie fetal programming by prenatal stress in humans. One early suggestion was a decrease in blood flow to the fetus. However, it is not clear if the decrease observed would be clinically significant, and others have failed to replicate the original finding. Another possible mediating factor is increased exposure of the fetus to cortisol, as has been shown in animal studies. Glucocorticoids (cortisol in humans and primates, corticosterone in rodents) are known to have a range of effects on the developing fetus. While they are essential for fetal development and tissue maturation, overexposure of the fetus to glucocorticoids can have effects that predispose to ill health in later life, such as a reduction in birthweight and epigenetic changes in the brain (Harris and Seckl, 2011).

Fetal overexposure to glucocorticoids could occur through an increase in maternal cortisol associated with anxiety and stress, which then crosses the placenta into the fetal environment. In animal models, this has been shown to be one mechanism. If pregnant rhesus monkeys are hormonally stimulated to have increased cortisol production, there are altered offspring neurodevelopmental outcomes, similar to those seen in response to prenatal stress. The effects of prenatal stress in rats have been shown to be prevented by removing the adrenal gland, and, at least for some outcomes, reinstated by corticosterone administration. However, the human hypothalamic–pituitary–adrenal (HPA) axis which makes cortisol functions differently in pregnancy from in most animals. The maternal HPA axis becomes gradually less responsive to stress as pregnancy progresses. Only a weak, if any, association between maternal mood and her cortisol level exists, especially later in pregnancy. It thus seems unlikely that an increase in maternal cortisol is the major mediating mechanism between prenatal maternal stress, anxiety or depression in later pregnancy, and altered fetal development.

It is possible that the effects of prenatal stress on fetal programming are mediated by cortisol without increases in maternal levels. An alternative explanation is that stress or anxiety causes increased transfer of maternal cortisol across the placenta to the fetus. The placenta clearly plays a crucial role in moderating fetal exposure to maternal factors and presumably in preparing the fetus for the environment in which it is going to find itself (O'Donnell et al., 2009). Thus another mechanism by which the fetus could become overexposed to glucocorticoids is through changes in placental function, especially the enzyme 11β-hydroxysteroid dehydrogenase type II (11β-HSD2), the barrier enzyme which converts cortisol to the inactive cortisone. If there is less of this barrier enzyme then the fetus will be exposed to more maternal cortisol, independently of any change in the maternal cortisol level. There is some evidence in both rat models and in humans that prenatal stress can indeed reduce placental 11β-HSD2.

Maternal cortisol is correlated with fetal cortisol levels, and so higher maternal levels will result in higher fetal levels. It is thus possible that both maternal cortisol and maternal anxiety/depression are independent determinants of fetal exposure, with the maternal anxiety inducing increased placental permeability to the raised cortisol. There is some evidence that this is the case. The question remains of what changes in maternal chemistry, associated with maternal mood in pregnancy, have this influence on placental function. One possibility is the group of chemicals called the cytokines, which are involved in the immune system and in inflammation. Psychosocial stress during pregnancy has been shown to be associated with raised levels of inflammatory cytokines such as interleukin-6. Although, how, if at all, these affect placental function remains to be determined.

The level of cortisol in the amniotic fluid, surrounding the baby in the womb, has been shown to be inversely correlated with infant cognitive development at about 18 months. The higher the cortisol in the amniotic fluid, the lower the infant performance on a baby IQ test. However, the study also measured the attachment between the mother and baby and found that this inverse relationship was strong in insecurely attached infants but absent in the securely attached. This suggests that the quality of attachment may be able to buffer against, at least this effect, of raised *in utero* cortisol. The quality of the postnatal mothering is as important as what happens in the womb.

Epigenetic changes, which involve reversible changes to the structure of DNA, such as the addition of a methyl group, control the amount of mRNA and protein produced. Such epigenetic changes can be induced by the environment and may underlie many of the processes of fetal programming. Prenatal stress has been shown to cause epigenetic changes in the rodent brain, in the DNA codes for the receptor which binds the stress hormone corticosterone. In humans, stress during pregnancy caused by violence from the partner has been shown to cause epigenetic changes in the DNA for this same receptor in the blood of their adolescent children. This suggests that the HPA stress responses in these children may be augmented, and this in turn may underlie an increased vulnerability to anxiety or depression.

However, several other biological systems are likely to be involved as well as that producing cortisol. Serotonin (also known as 5-hydroxytryptamine) is another possible mediator of prenatal stress-induced programming effects on offspring neurocognitive and behavioral development. During gestation serotonin acts as a trophic factor regulating cell division,

differentiation, and synaptogenesis. Animal studies have shown that increased serotonin exposure during gestation is associated with alterations in many neuronal processes and subsequent changes in offspring behavior. Recent work has identified an endogenous serotonin biosynthetic pathway in the human placenta, suggesting a possible role for alterations in placental serotonin in human fetal programming.

Implications for Intervention

The main implication arising from the evidence of the potentially harmful effects of stress during pregnancy on the child is to improve the emotional care of pregnant women. While the physical care of pregnant women has improved dramatically over the last century, their emotional care has not. It is still true that most anxiety, depression, and emotional and physical abuse experienced by pregnant women is undetected by health professionals and little help seems to be available, even in the developed world. In the developing world, the situation is even worse. It is not sufficiently known that symptoms of anxiety and depression are at least as common during pregnancy as postnatally and domestic abuse can increase. Midwives and obstetricians need to be trained to detect all this and refer women to further appropriate help when needed. Up to 15% of pregnant women and their children would benefit from relevant extra support. For most depressed or anxious women, some sort of counseling or talking therapy, such as cognitive behavioral therapy, will be most suitable. For the more severely depressed, antidepressants may be the best option.

The magnitude of the increased risk to the child is clinically significant, although most children of stressed mothers are not affected, and those that are, are affected in different ways. In the large population Avon Longitudinal Study of Parents and Children study, it was found that if the mother was in the top 15% for anxiety, her child was at double the risk for emotional/behavioral problems later (O'Connor et al., 2002). The risk was raised from about 5 to 10%. Similar results have been found more recently for prenatal depression. The effects of prenatal stress on cognitive development also appear to be clinically significant. In a study correlating prenatal life events with child cognitive development at 17 months, Bergman et al. (2007) found that prenatal stress accounted for 17% of the variance in cognitive ability, after allowing for a range of confounders, including postnatal maternal mood. Prenatal partner relationship strain accounted for most of the life event stress-related variance in cognitive ability. If the woman said she had suffered from three or more prenatal partner-related life events (e.g., 'your partner was emotionally cruel to you') her infant had a mean Mental Developmental Index of 89, compared with 98 for the rest of the group (the general population norm being 100).

As maternal stress during pregnancy increases the risk for an adverse outcome for the child, interventions to reduce such stress should improve the outcome. There has not yet been any study of an intervention specifically designed to reduce maternal stress in pregnancy with a follow-up study of outcome for the child. The only intervention which starts during pregnancy and which has included long-term follow-up studies of the child is the Nurse Family Partnership (Olds et al., 2004). This is targeted at deprived especially teenage and poor single mothers and includes multiple home visits by specially trained nurses during pregnancy and for the first 2 years. It was not designed to target stress but help the mothers with diet, health care, their own education, reduction in smoking, and with parenting. However, these special nurses do provide much support for these mothers from early pregnancy onward. The results of this intervention have been impressive, with many long-term improvements in self-care, parenting behavior, and child outcome. A notable finding was a reduction of criminal behavior, especially in girls. Relative to the comparison group, by 19 years of age, girls in the pregnancy and infancy nurse-visited group were less likely to have been arrested and convicted. There was no comparable benefit for boys. As prenatal stress causes an increased risk for conduct disorder, ADHD and cognitive problems, and all these are major risk factor for later criminal behavior, one would expect a reduction in prenatal stress to reduce crime as well as improving other outcomes. It may be that, for boys, a 'top up' intervention in the teenage years is needed.

Although there have been no long-term follow-up studies on the child of interventions that start in pregnancy, apart from the Nurse Family Partnership, there have been several studies of interventions that reduce aspects of stress during pregnancy. Interpersonal therapy has been shown to be effective at reducing depression in pregnant women. Listening to music has been found to decrease maternal plasma cortisol and self-reported state anxiety score in women awaiting amniocentesis. Maternal relaxation has also been shown to improve indices of fetal neurobehavior, such as heart rate variability. One study compared active (directed by a therapist) and passive (sitting in a chair) relaxation. Both active and passive relaxation significantly reduced self-rated anxiety and maternal heart rate, but the effect was significantly greater with the active relaxation. In contrast, the passive relaxation significantly reduced noradrenaline levels whereas active did not. Both methods significantly reduced cortisol. However, overall there was a striking lack of correlation between the psychometric and biological indices. In order to reduce specific biological effects of anxiety or depression during pregnancy, different methods may be needed from those that are most effective at reducing subjective psychological symptoms.

New studies on the ways of reducing stress during pregnancy, together with long-term follow-up studies of the child, are needed.

Stress in Adolescence: Effects on Development

Nada Krapić, Jasna Hudek-Knežević, and Igor Kardum, University of Rijeka, Rijeka, Croatia

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Adolescents frequently have to cope with various stressors that could be potential threats to their healthy development and well-being. Most important mental health consequences of stress in adolescence, such as depression, anxiety, suicide, substance use, and antisocial behavior are reviewed. Physiological mechanisms through which stress exerts its effects on health, as well as some physical health outcomes, such as somatic symptoms, immune changes, and illnesses (cancer, type 1 diabetes, and dermatological conditions) are described. Furthermore, the effects of cognitive appraisal, coping, and social support as mediating and moderating factors between stress and various health outcomes also are explained.

Adolescence is an important period of human development characterized by neurobiological, hormonal, psychological, and social changes. During this developmental period, adolescents have to cope with various common stressors, including physical and sexual changes related to puberty, school life demands, problems with initiating and maintaining friendships and romantic relationships, career choice and beginnings of their working life, and a gradual independence from their families. Additionally, some teenagers have to cope with more unusual stressors that could be related to family (e.g., mental or physical illness, death of a loved one, drug or alcohol abuse, parental separation or divorce), social problems (e.g., poverty, violence), as well as their individual problems (e.g., teenage pregnancy, serious illness, school failure, and various kinds of abuse). Therefore, adolescence often has been thought of as a time of storm and stress, a period of rebellion characterized by conflicts with parents. Contrary to the traditional considerations, however, more recent research findings support the view that storm and stress is not a universal and exclusively biologically based phenomenon (Susman and Rogol, 2004). Contemporary understanding suggests that adolescence is a period when specific types of stressors are more likely to occur than in other developmental periods and that these developmental changes also include adaptation to cultural expectations of becoming an adult. Nonetheless, adolescents frequently have to cope with various stressors that could be potential threats to their healthy development and well-being. For example, cumulative and chronic stressors may lead to increased emotional distress (e.g., depression, anxiety), antisocial behaviors (e.g., aggression, delinquency), risky health behaviors (e.g., substance use, risky driving), and physical health outcomes (e.g., physical symptoms, common colds). Traumatic stressors, such as physical, sexual, and relational victimization, may result in posttraumatic stress symptoms. Furthermore, many studies have found that stressful experiences exert short-term as well as long-term effects on adolescents' healthy development.

Mental Health Consequences of Stress in Adolescence

Depression

Research on recent birth cohorts showed that adolescence is one of the developmental periods during which depression most frequently occurs (Hammen, 2009). Although estimates of childhood depressive episodes for children under the age of 12 years vary from 1 to 3%, several studies found adolescence lifetime prevalence of major depression to be from 9.3 to 24.0% (Merikangas and Knight, 2009), with an additional 11% of adolescents reporting minor depression (Hammen and Rudolph, 2003). Longitudinal studies have found that depression in adolescence might have long-term negative consequences regarding some other mental disorders (e.g., anxiety disorders, substance use) and various negative outcomes (e.g., academic failure, teenage pregnancy, conflicts with family and peers, and suicide). Additionally, it has been found that among those with early onset of depression, very high percentages experience depressive episodes as adults and that early onset of depression is related to a wide range of psychiatric, physical, and functional health outcomes (Abela and Hankin, 2008).

Although the majority of stressful events do not lead to depressive episodes, most depressive episodes are preceded by stressful events. Exposure to stressful events, such as parental death, serious illness, and sexual and physical abuse, as well as less traumatic events and hassles are frequently found to be risk factors for depressive symptoms and disorders in both clinical and community samples of children and adolescents. For example, a review of 60 studies exploring the associations between stressors and psychological problems, including depressive symptoms in children and adolescence showed that stressful experiences predict increases in mental health problems over time (Grant et al., 2004). It has been found that stress and depression are bidirectionally influenced, that is, those with depression histories have greater chance to experience additional distress in the future. A better understanding of the reciprocal influence of stress and depression may

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23031-6

have important implications for the course, treatment, and prevention of depression.

Strong evidence exists for gender differences in depressive disorders in adolescence. Recent meta-analysis reveals a higher prevalence of depression among teenage adolescent girls compared with boys (Costello et al., 2006). One longitudinal birth-cohort study found gender difference in major depressive episodes, with girls having higher rates of depression beginning from age 13 years, with this difference becoming more pronounced by age 15 years (Hankin et al., 1998). Therefore, it seems that the gender difference in depression emerges between ages 12 and 15 years, and by early adulthood women are twice as likely as men to experience depressive episodes. Several biological and psychosocial factors that can explain this difference have been identified. Besides biological risk factors (e.g., dysregulation of the hypothalamic-pituitary-adrenocortical (HPA) axis, genetic factors, and dysregulation of neurotransmitter systems regulating mood), psychosocial risk factors (e.g., negative cognitive style, interpersonal orientation, and negative life stress) also proved to be important (Hilt and Nolen-Hoeksema, 2009). Namely, many studies demonstrated that girls are exposed to greater levels of stressors, as well as that they report more interpersonal stressors compared with boys who report more academic stressors (Hammen, 2009). Girls also more often than boys are the victims of physical and sexual abuse, with both types of abuse being risk factors for the development of depression. Additionally, girls appear to generate more dependent stressors that contribute to their depression, and they are more reactive to stress than boys. Research results consistently show that under high levels of stress, girls have greater tendency to express depressive symptoms than boys.

Anxiety Disorders

Anxiety and depression share important features, but are nevertheless distinguishable phenomena. Although most fears during childhood and adolescence are considered appropriate for the developmental periods and the situations in which they occur, and although anxiety usually is thought of as adaptive because it helps in anticipating threat or harm, its clinical expression usually refers to developmentally inappropriate fears or to those that are developmentally appropriate but that produce excessive distress or dysfunction (Moore et al., 2010). Anxiety disorders usually begin relatively early in life, often manifesting before late adolescence.

Epidemiological data show that the anxiety disorders often are evident in children and adolescents. Overall, lifetime prevalence estimates in children and adolescents for any anxiety disorder range from approximately 10 to 20% (Costello et al., 2004). Specific types of anxiety disorders, such as panic disorder (PD), specific phobias, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, separation anxiety disorder (SAD), and generalized anxiety disorder (GAD) occur with different frequency during the period of childhood and adolescence. Epidemiological studies show that GAD is the most common, followed by SAD, social phobia, and the specific phobias. Much less frequent are PTSD, OCD, and PD, with less than 1% prevalence in population samples. Considering gender differences, research shows that girls are affected more, and the overall gender ratio for anxiety disorders throughout childhood and adolescence is ~2:1 (Costello et al., 2004). Untreated anxiety disorders tend to become chronic, with only a minority of adults (12–30%) exhibiting spontaneous remission. Adolescents show somewhat higher rates of recovery, and the majority of early onset anxiety disorders remit by early adulthood.

Early anxiety disorders, however, especially those that develop in late adolescence, represent major risk factors for the development of anxiety disorders in adulthood. Several disorders, such as PD, social phobia, GAD, and OCD, frequently manifest waxing and waning symptoms in which the exacerbation of symptoms may be related to stressful experience (DSM-IVTR; APA, 2000).

Ample evidence indicates that the most prominent factors that contribute to the development and maintenance of anxiety symptoms and disorders are biological predispositions (e.g., family-genetic, neurobiological, and hormonal), but environmental factors should not be underestimated. Namely, although more consistent findings were obtained for depressive disorders, many studies showed that children and adolescents who are exposed to chronic stressors and unpredictable circumstances may be at greater risk for developing anxiety disorders. Research suggest that GAD may result after family relocations, school changes, or other stressful life events (Vasey and Ollendick, 2000), although stressful events related to health and family discord are predictive of increases in anxiety sensitivity (McLaughlin and Hatzenbuehler, 2009). Parenting practices also may lead to anxiety disorders. For example, overprotective parents usually reinforce avoidant and inhibited behavior in their children encouraging them to perceive many situations as new or negative, which in turn lead to their impaired ability to cope and raises their anxiety. Furthermore, a moderate degree of specificity exists in the associations between types of life events and types of anxiety disorders. For example, it has been found that parental separation was related with GAD, while parental death was related with increased risk for phobia (Kendler et al., 1992).

Prevailing theoretical models of the causes of internalizing disorders (depression and anxiety) are variants of diathesis-stress models. The fundamental assumption of a diathesis-stress model is that both the diathesis (also interchangeably referred to as vulnerability) and various environmental conditions (e.g., stressors) are necessary for the development of a disorder and that neither one alone is sufficient. Therefore, it is assumed that internalizing symptoms results from the interaction between different vulnerabilities (e.g., neurobiological, genetic, cognitive and environmental) and stressful events.

Suicide

According to the World Health Organization (2001), suicide is one of the three leading causes of death among people from 15 to 34 years of age in all countries. The results of a meta-analysis of 128 studies from different countries showed that 10% of youths reported a suicide attempt, and 20–30% reported suicidal ideations at some point in their life (Evans et al., 2005). The higher rate of death by suicide is

observed in adolescent boys, while after puberty adolescent girl show higher rates of suicidal ideation and suicide attempts.

The strongest risk factors for attempted and completed suicide in youth are previous suicide attempts, suicidal ideation, and the presence of psychiatric disorders, especially depressive disorder, alcohol and drug abuse, conduct disorder, and aggressive-impulsive behavior (Gould et al., 2003).

Furthermore, environmental stressors also have been recognized as having a role in suicide attempts and suicidal ideation. For example, several studies have found that life events, such as interpersonal loss and legal or disciplinary problems have been linked to completed suicide (Jacobson and Gould, 2009). Childhood physical abuse (e.g., corporal punishment), sexual abuse, and neglect also have been related to suicidal behavior. The younger the person was at the time of the first abuse, the higher the number of suicide attempts reported (Berk et al., 2010).

Bullying also is linked to suicidal behavior among adolescents, especially girls, as indicated by a large epidemiological study showing that bullying perpetrators and their victims, as well as youth who are both victims and perpetrators, have a higher risk for suicidal ideation and suicide attempts (Brunstein-Klomek et al., 2007). Parental conflict is found to be related more frequently to suicide in younger adolescents, whereas romantic relationship difficulties are associated more strongly with suicide in older adolescents (Brent et al., 1999).

Neither psychiatric disorders nor stress alone, although important, are sufficient to trigger suicidal behavior. It is likely that the combination of underlying psychiatric disorders paired with an acute stressor typically leads to suicide.

Substance Use

Adolescence is a period of life characterized by the experimentation with risky behaviors and is a critical developmental period for the onset of substance use and, sometimes, the beginning of the trajectory toward substance dependency. Evidence shows that approximately 50% of adolescents have tried an illicit drug at least once before the end of their high school education, more than 75% have tried alcohol, and approximately 60% of high school seniors report some experience with cigarette smoking, with 19% of them being daily smokers (Johnston et al., 2001, 2002). Substance use and addictive disorders are topics of great importance because of their pervasive negative consequences that may affect the course of adolescent development as well as outcomes in adulthood. For example, accidents, suicides, and homicides account for more than 80% of adolescence deaths, of which at least 50% include drugs and alcohol (Soderstrom and Dearing-Stuck, 1993). Studies also suggest that long-term consequence that is most reliably related to substance use in adolescence is the continued use of that substance. It has been found that adolescence substance use is associated with psychological distress and mental health problems in adulthood.

Research shows many risk factors for drug abuse, each having a different impact depending on the phase of development. These factors can be related to individual characteristics (e.g., genetic susceptibility to addiction, high sensation seeking and impulsivity, alienation, academic failure, and low commitment to school), as well as environmental stressful events (e.g., family problems, problems with peers and community environment).

Studies consistently have found that adolescents who experience high levels of life stress are more likely to use alcohol or drugs and to increase the quantity and the frequency of substance use over time (Chassin et al., 2004). The most frequent explanation of the role of stress in substance use is that adolescents who experience high level of stress and negative affect use alcohol or drugs as a way to decrease them. This is in accord with research findings showing that emotional distress, negative affect, and clinically diagnosed depression are associated with adolescent substance use, although some results show that negative affect might be a result, rather than a cause, of adolescent substance use.

Furthermore, although substance use often is considered as a motivation to reduce negative affect, it also is seen as a way to increase positive affect (Chassin et al., 2004). This distinction in the motive for substance use is important because it has been suggested that adolescents who use substances to maintain or enhance positive affect may use them moderately in quantity and frequency, whereas those who use substances to decrease negative affect may use them more excessively.

Antisocial Behavior

Among several types of mutually intercorrelated antisocial behaviors the most important are conduct disorder, aggression, and delinquency. They are related logically and empirically and, therefore, risk factors that apply to one of them also likely apply to the other two (Farrington, 2004). The prevalence estimates for antisocial behaviors in adolescence are usually very high. For example, the prevalence of conduct disorders in adolescent boys varies from 6 to 16%, and in adolescent girls it ranges from 2 to 9% (Mandel, 1997).

The etiology of antisocial behaviors includes multiple risk factors that do not occur in isolation. They can be grouped into individual, family, and extrafamilial factors (Connor, 2002). Genetic factors and individual differences in temperament are the most important individual factors. Among family and extrafamilial risk factors, chronic and acute stressful life events are predominant. Several family factors found to be strongly associated with antisocial behaviors are severe marital discord, overcrowding or large family size, paternal criminality, maternal psychiatric disorder and the family history of admission of a child into the care of local child protective services. Extrafamilial risk factors for antisocial behaviors include relationship with peers, social deprivation, neighborhood violence, and media violence (Connor, 2002). Except for heritable genetic factors, the majority of risk factors are nonspecific. Namely, they increase the risk for wide variety of general adolescent psychopathology, including different types of antisocial behaviors. Research also suggest that cumulative effects of multiple risk factors exert a much stronger influence on antisocial behavior in children and adolescents than any specific type of risk factors.

Physiological and Physical Health-Related Consequences of Adolescent Stress

When an event has been appraised as stressful, our body triggers a sequence of physiological reactions. Physiological stress response and its control are regulated by the two axes of the neuroendocrine system: HPA and sympathetic-adrenal-medullary (SAM) pathways. The activation of the SAM axis is related strongly to acute emotions, such as fear and anger, and describes the first part of the stress response. During stress, the hypothalamus helps the body to prepare for 'fight or flight' by triggering sympathetic impulses to various organs, stimulating the release of epinephrine, norepinephrine, and other catecholamines in the blood circulation. Catecholamines can cause changes in blood pressure, heart rate, sweating, and pupil dilatation, which result in a feeling of arousal. They also have an effect on a variety of body tissues and can lead to changes in immune function. In addition to the sympathetic activation, stress also triggers changes in the HPA system. At the same time that sympathetic activity increases, the hypothalamus releases corticotropin-releasing hormone, which stimulates the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH), which increases the adrenal cortex's secretion of cortisol. Cortisol supplies cells with amino acids and extra energy sources and diverts glucose from skeletal muscles to brain tissue. Stress also stimulates the release of glucagon from the pancreas, growth hormone from the anterior pituitary, antidiuretic hormone from the posterior pituitary gland, and renin from the kidneys. Through feedback to the hypothalamus, epinephrine can increase secretions of ACTH to higher levels and thus can maintain the increased activation of HPA axis (Tsigos and Chrousos, 2002). The neurohormonal and immune changes that develop during stress are physiological pathways through which stress can lead to mental and physical health outcomes.

Many factors during adolescence simultaneously contribute to the heightened sensitivity to stressful events, especially neurobiological processes, such as the continued maturation of stress-responsive brain regions, the changes in hormonal reactivity, and the quantity and quality of stressful events. For example, research shows that gender differences in the functioning of stress-related physiological pathways begin during adolescence and persist into adulthood. Available evidence suggests that HPA response in girls differs from those in boys, generally, and is more under the influence of genetic factors and previous environmental exposures. Studies suggest that variants in specific genes, parental depression, and stressful events affect cortisol responses in girls more than those in boys. A greater reactivity to internal and external influences under stress than may be adaptive in many situations also might be related to risks (e.g., increased probability of depression) (Oldehinkel and Bouma, 2011).

Most studies dealing with the impact of stress on adolescent health and psychological well-being have found that adolescents suffer from a large number of body complaints that might be considered as psychosomatic symptoms (e.g., headaches, stomachaches, indigestion, circulatory problems, and nausea). Among those most frequently reported are abdominal pain, chest pain, and headaches (Seiffge-Krenke, 1998). There are indications that daily hassles are better predictors of somatic symptoms than major life events. Among stressful situations that are most important for elevated somatic symptoms in this developmental period are school-related stressors, such as interpersonal problems with peers and teachers, schoolwork pressure, and fear of school failure. Additionally, the transition from primary to secondary school, as well as conflicts with parents, are stressful experiences that in many adolescents increase the frequency and intensity of somatic health symptoms.

Stress also leads to a significant decrease in the function of cellular immunity such as lower NK-cells activity, lower lymphocyte proliferation, and production of gamma interferon (IFN-γ), as well as the increases in herpes virus antibody production. These changes are related to a greater susceptibility to infectious diseases, such as herpes reactivations, infections of the upper respiratory tract, and HIV infections. Exam stress, a stressor typical for adolescents, frequently leads to these immune changes and related infectious diseases (Kiecolt-Glaser et al., 2002).

Research also shows that stressful life events have an impact on chronic illnesses in adolescents. Especially high incidence of stressful life events has been found in children and adolescents with cancer, who most frequently reported the experience of marital separation, death of a close family member, change in residence, and change in health of family members before the onset of cancer (Seiffge-Krenke, 1998). Although these findings could not be considered as evidence of causal relations between stressful events and diseases, and although physiological mechanisms of these associations are not fully understood, it seems that not a single event, but rather the accumulation of several major stressors, could have negative effects on health outcomes.

Although the strongest associations between life events and the onset of chronic illness have been found in cancer patients, the negative impact of life events also was found in patients with other chronic diseases. Studies on diabetic patients also show greater frequency of stressful life events before the onset of diabetes, and it has been found that stress could contribute to the onset of type 1 diabetes through its effects on the immune function (Cox and Gonder-Frederick, 1992). Furthermore, higher levels of diabetes-specific stress as well as general stress are associated with less adherent behavior and subsequently more problems with metabolic control, at least in patients with type 1 diabetes (Farrell et al., 2004).

Stress can be an important factor in the onset, clinical course, and asthma-related mortality. For example, stressful life events such as family dysfunction and patterns of behavior that increase psychological conflict as well as stressful school exams can accelerate the onset and recurrence of asthma after the remission. Furthermore, studies have found that children and adolescents from socially isolated families have more frequent symptoms of asthma, more days of restricted activities because of the symptoms, worse illness management, and more frequent visits made to physicians (Wright et al., 1998). It seems that high levels of ongoing chronic stress plus an acute negative life event could be an especially important risk combination for an asthma attack in children and adolescents. Research highlights immune mechanisms through which psychosocial variables, such as stress, may plausibly affect asthma outcomes. For example, stress has

been linked to inflamed bronchial pathways implicated in asthma (Chen et al., 2006).

Psychosocial stress also has been related to the onset or worsening of various dermatological disorders. It may influence dermatological symptoms in primary stress-reactive skin disorders in which neuroendocrine and psychoneuroimmunologic factors have a crucial role (e.g., psoriasis, atopic dermatitis or eczema, urticaria, acne, and alopecia areata), in disorders characterized by physiological response (e.g., excessive perspiration and blushing), as well as in skin disorders resulting from psychiatric condition such as OCD, PTSD, or major depressive disorder (e.g., dermatitis artefacta, neurotic excoriations, or trichotillomania) (Gupta, 2010).

Stressful events frequently experienced by adolescents, such as exams, have been found to worsen some dermatological diseases (e.g., acne). Additionally, an increase in distress is related with the increase in acne severity. Acne has a peak incidence during adolescence, a period typical for intensive preoccupation with body image and appearance. Therefore, besides the contribution of psychosocial stress to the onset of dermatological disease, the disease itself may result in significant stress for the patient. For example, in vulnerable adolescents, even mild acne could result in severe depression.

Several neurophysiological mechanisms have been implicated in stress-mediated skin disorders. Because stressful emotional experiences disturb the regulation of the HPA and the SAM systems, they may result in the alternations of glucocorticoid levels. For example, studies have found a relation between stress and an imbalance in the epidermal permeability barrier function, which is mediated by the increase in endogenous glucocorticoids. Additionally, higher anxiety in acne patients have been associated with high blood catecholamine levels, which decreased with the treatment of the acne, suggesting that the anxiety in acne patients is associated with the SAM system activation (Gupta, 2010).

Effects of Cognitive Appraisal, Coping, and Social Support on the Experience of Stress

The same stressful event in different individuals may lead to the distress of various intensities. What is extremely stressful in one individual may not be at all stressful in another. Among the most important sources of variation in the effects of stress during adolescence are personality traits, cognitive appraisal, coping with stress, and social support. According to the transactional model of stress and coping, the appraisal of a situation determines the degree of stress experienced by the individual (Lazarus and Folkman, 1984). The model describes two main types of cognitive evaluations of stressful situations, primary and secondary appraisals. Primary appraisal includes the individual's assessment of the stressfulness of the situation. Situations appraised as stressful can involve harm, loss, threat, or challenge. Secondary appraisal includes the individual's assessment of controllability of the stressful episode and the choice of coping strategies. These two types of appraisals are parallel processes that may be automatic and usually occur without conscious awareness. Coping is most often defined as constantly changing cognitive and behavioral efforts to manage specific external or internal demands that are appraised as taxing or exceeding the resources of the person (Lazarus and Folkman, 1984). According to this theory, coping efforts are broadly classified into two types: problem-focused and emotion-focused coping. Problem-focused coping can be directed outward to alter some aspect of the environment or inward to alter some aspect of the self. They include cognitions and behaviors directed toward analyzing and solving a problem and may as well include dividing the problem, seeking information, and considering alternative courses of actions as well as direct action. The efforts directed toward self are various forms of reappraisals, such as changing the meaning of the situation or event, reducing ego involvement, or recognizing the existence of personal resources or strengths. Emotion-focused coping strategies are directed toward decreasing emotional distress. They include various ways of coping usually described as expression and suppression of emotions as well as seeking emotional support from others. Besides problem- and emotion-focused coping, avoidance coping also is included in some taxonomies of coping with stress. It refers to cognitive or behavioral avoidance or denial of the problem.

During puberty and adolescence, the differentiation of coping resources, skills, and strategies oriented toward problem solving are under the influence of cognitive development and social experience. Adolescence is a period in human life characterized by a relatively quick development and the use of a broader range of coping strategies, as well as the tendency to abandon ineffective coping. For example, between 13 and 15 years of age, a significant decrease of avoidance coping has been noted. Also, it has been observed that older adolescents use wishful thinking and distancing less than before. Adolescence is also a critical period for the development of some ineffective coping strategies, especially social withdrawal and alcohol and substance use (Aldwin, 2007). Regarding gender differences, the most consistent result found in the literature is that girls use emotion-focused coping more often than boys. To the lesser extent, this is also true for problem-focused coping. This usually is explained by their faster maturation and the experience of higher levels of stress during early adolescence when compared with boys. Also, it has been found that boys use drugs, alcohol, and repressive coping more often than girls.

Among major antecedents of coping with stress are individual differences in temperament and other personality traits as well as in self-concept. These factors influence the availability of coping strategies in stressful situations as well as the appraisal of the stressfulness of events. For example, the majority of research shows that the personality trait of extraversion is related to active and more efficacious coping strategies, such as problem-focused coping, whereas neuroticism is related to passive and less efficacious coping strategies, such as avoidance. Neuroticism is related to higher exposure and reactivity to stressful events and also is considered to be a disposition for stressful experience even in the absence of stressors. Furthermore, adolescents who are high in self-esteem usually adopt problem-focused coping strategies, whereas adolescents with low self-esteem often adopt avoidant and emotion-focused coping strategies.

Coping strategies are not defined as generally effective or ineffective, but rather their effectiveness may depend on the type of situation, specific combinations between different coping strategies, and timing in their use during the course of a stressful transaction. For example, avoidance strategies are more effective in reducing emotional distress in the short term, and problem-focused strategies are more effective over the long term. When the stress is perceived as controllable, problem-focused coping strategies are associated with fewer psychological symptoms, whereas in uncontrollable stressful situations, emotion-focused coping is related to fewer symptoms.

Considering various health consequences of coping with stress, numerous studies show that some coping strategies more often are related to positive, whereas others to negative, health outcomes. For example, longitudinal research on adolescents reveals that the use of avoidance and emotion-focused coping have been linked with more intensive depressive and anxiety symptoms, whereas the use of problem-focused coping has been associated negatively with depression and hopelessness. Furthermore, problem-focused coping has been found to correlate negatively with health problems and health risk behaviors, whereas avoidance coping correlated positively with these domains (Wilson et al., 2005). Generally, it could be concluded that when adolescents lack adequate coping skills, there is a risk from various negative consequences, including psychological distress and suicidal attempts, smoking and substance use, and high-risk sexual behaviors (Rew, 2005).

Social support is considered to be one of the most important psychosocial factors that influence the relationship between stress and health outcomes. It has been defined broadly as interpersonal social resources that involve either the presence or the implication of stable human relationships. Social support is regarded as structural (e.g., number of social contacts, size, and density of social networks) or functional (e.g., informative, emotional, instrumental). Evidence suggests that social support generally contributes to better adjustment of adolescents and that their low satisfaction with social support is associated with anxiety, depression, psychosomatic symptoms, and interpersonal sensitivity.

The protective roles of social support on health outcome are explained by the two models. The main-effect model states that social support has independent effects on mental and physical health outcomes regardless of the level of stress experienced, while the stress-buffering model posits that social support has indirect effects on health outcomes by acting as a buffer against stress (Cohen and Wills, 1985).

Among adolescents, the social support of family and peers has great significance. Parental support has been found to be a predictor of better adjustment and less distress in adolescence. The presence of familial social support has been associated with higher levels of resilience. On the other hand, different studies show that two characteristics of a risky family social environment – conflict and aggression and a cold, unsupportive, or neglectful home – have adverse developmental effects on adolescents. It has been shown that parental support, involvement, and monitoring reduce the probability that adolescents will engage in a variety of health-compromising behaviors. Furthermore, longitudinal studies have found that lack of support and deficient nurturing during childhood leads to higher rates of illness and physical complaints several years later (Repetti et al., 2002).

Without the support of a peer group, adolescents experience loneliness and a sense of lack of belonging and acceptance, which, in turn, can contribute to frustration and feelings of rejection and emergence of antisocial behavior. Along with positive effects of the peer support, adolescence is also a period during which relationships with peers can undermine healthy development. For example, drug use and risky sexual behavior may be influenced greatly by peers. Regarding drug use, adolescents who become involved with substance use usually have friends who do the same.

Social support most effectively acts as a buffer against stress when it matches the needs elicited by a stressful event. Even social relationships that are close and supportive are not uniformly positive and may have negative consequences. For example, being close to and having highly supportive antisocial parents might result in various types of problematic behaviors of adolescents, such as substance abuse or conduct disorder (Rook, 2003). Also, it has been found that diabetic adolescents who turn to their peers for coping strategies may have worse metabolic control than those who turn to their parents (Aldwin, 2007).

Cross-Cultural Differences in the Effects of Stress on the Development of Adolescents

As mentioned, developmental changes during adolescence, among other factors, also include adaptation to cultural expectations of becoming an adult. The greatest part of our knowledge about the effects of stress on development in adolescence was drawn from the research on the samples from Western societies. Theoretical assumptions as well as empirical evidence suggest the existence of cultural differences in the effects of stress on the adolescent development. Cultures differ in the norms, beliefs, and values that provide prescriptions for behavior and therefore have a different impact on the stress process. Aldwin (2007) stated that culture can affect the stress and coping process in four ways. It shapes the types of stressors that a person is likely to experience, affects the appraisal of the stressfulness of a given situation, affects the choice of coping strategies, and provides different institutional mechanisms by which a person can cope with stress. Furthermore, because of the intercultural exchange that has increased markedly over the past several decades throughout the world, the problem of acculturative stress has become highly pronounced. Also, it has been emphasized that stress increases with rapid social change, most often in the form of westernization and a change in values (e.g., individualism, competition, and consumerism) (Dasen, 2000).

Considering ethnic differences in the stress consequences, Dornbusch et al. (1991) have found significant relationships between stressful life events and symptoms of depression among Asian and African American, Latino, and white adolescents, but the relationship was the weakest for African Americans. Similarly, Gerard and Buehler (2004) have found that the relationship between risk factors and depression in adolescence was moderated by racial–ethnic group membership and that this relationship was stronger

for whites compared with both blacks and Latinos. Also, rates of completed as well as attempted suicide vary according to ethnicity. For example, the elevated rates of suicide among Native American youth are supposed to be associated with low social integration that results in limited access to various resources. On the other hand, lower rates of suicide among African American youth have been associated with their higher levels of religiosity compared with white youth. Highest levels of suicidal ideation and attempts are found in Hispanic females and can be attributed to a combination of cultural factors, including familism, authoritarian parenting style, and conflicts with caregivers over the issue of individuality (Jacobson and Gould, 2009). Comparing adolescent coping behaviors from seven different European nations, Gelhaar et al. (2007) found the highest cultural differences for coping with job-related problems, while similarities were found for coping with self- and future-related problems. Cross-cultural differences in quality and availability of social support also should be taken into account. Namely, despite social change, stress of adolescents is reduced more efficiently in those societies that manage to maintain a strong cultural identity and a part of their value system, such as family solidarity.

Conclusion

Although studies on the effects of stress on development of adolescence are numerous, more longitudinal and integrative research is needed to broaden our understanding of how complex relations between stress and mediating and moderating processes (personality, cognitive appraisal, coping, social support) exert their effects on (un)healthy development of adolescents. Also, the problem of the lack of comprehensive research exploring the factors associated with ethnicity that influence the relationship between stress and adolescent health is becoming more and more pronounced because the current intercultural exchange has considerably increased worldwide.

It is well known that stressful experience can lead to long-term changes in the body by destabilizing different physiological pathways, which often result in various mental and physical health outcomes. Therefore, knowledge of the deleterious effects of stress on adolescent health outcomes may be of help in planning and organizing prevention and treatment programs and thus improve adolescents' quality of life.

Stress in Childhood: Effects on Development

Abstract

Stressful events can occur at any point in child and adolescent development. Events that can cause stress include parental divorce, sexual or physical abuse, severe accidents, cancer or other life-threatening illness, natural or man-made disasters, war, terrorism, or the sudden death of a parent, sibling, or peer. However, not every child exposed to a traumatic event develops stress-related symptoms. Many children demonstrate resiliency, the ability to thrive and excel even when exposed to severe stressors. This article discusses the types of stressors that may impact upon children throughout the world, details the effect of stress on development, and discusses other factors that may either exacerbate or minimize the effect of stress on development.

Unfortunately, stressful events are not an unusual occurrence in child and adolescent development. Parents divorce, grandparents die, children and others in their lives get injured. These may not be considered extreme trauma, however. According to the *Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition, Text Revision* (*DSM-IV-TR*; American Psychiatric Association, 2000), an extreme traumatic stressor is one that involves

> direct personal experience of an event that involves actual or threatened death or serious injury, or other threat to one's physical integrity; or witnessing an event that involves death, injury, or threat to the physical integrity of another person; or learning about unexpected or violent death, serious harm, or threat of death or injury experienced by a family member or other close associate. (p. 463)

Examples include sexual or physical abuse, severe accidents, cancer or other life-threatening illness, natural or man-made disasters, war, terrorism, or the sudden death of a parent, sibling, or peer (Cohen et al., 2006a). However, it should also be noted that not every child exposed to a traumatic event will develop stress-related symptoms. Many children demonstrate resiliency, the ability to thrive and excel even when exposed to severe stressors (Leckman and Mayes, 2007). It is the intent of this article to discuss the types of stressors that may impact upon children throughout the world, detail their effects on development, and discuss other factors that may either exacerbate or minimize their effects on development.

Incidence of Stress-Inducing Incidents in Children

Children and adolescents may encounter a number of different experiences which may induce a stress response. These can include direct experience of abuse (e.g., sexual, physical), grief, domestic and community violence, wars, terrorism, natural disasters, or a combination of these (Little et al., 2009). In a retrospective study of over 17 000 adults, Felitti et al. (1998) reported that more than one half of their sample had experienced at least one adverse event in childhood with approximately one quarter reporting having experienced two or more. Clearly, exposure to possible stress-inducing events is not uncommon in childhood. Increasing numbers of children and adolescents have also been victims of natural disasters. For example, in 2011 there were 63 earthquakes worldwide of 6.0 magnitude or greater (United States Geological Survey, 2012). This includes a magnitude 9.0 earthquake off the coast of Honshu, Japan which resulted in at least 15 550 people killed, 5344 missing, 5314 injured, 130 927 displaced, and at least 332 395 buildings, 2126 roads, 56 bridges, and 26 railways destroyed or damaged by the earthquake and resultant tsunami (United States Geological Survey, 2012). The past decade has also seen earthquake-induced tsunamis that have caused devastation in countries bordering the Indian Ocean and, more recently, in Chile and Samoa and hurricane-related devastation in many islands of the Caribbean as well as the central Gulf Coast of the United States (i.e., New Orleans), Florida, and the US northeast (i.e., New Jersey and New York). In addition, there have been major floods on virtually every continent and destruction caused by cyclones and other natural disaster throughout the world. While there are similarities across natural disasters, each is unique in some way, which, in turn, may influence the type of reaction of the victims (Evans and Ohlner-Stinnett, 2006). One thing is clear, however, natural disasters are a common source of stress in childhood, resulting from a loss of property, displacement, and disruption of the normal routine (e.g., attending school).

Child sexual abuse is another source of trauma and stress in children. A 1998 meta-analysis found that in the United States the incidence of sexual abuse ranged from 3 to 37% for boys and 8–71% for girls with an average of 17% for boys and 28% for girls (Rind et al., 1998). In addition, the US Department of Education estimates 9.6% of students are targets of educator sexual misconduct sometime during their school career (Shakeshaft, 2004). In the United Kingdom, it is estimated that 11% of boys and 21% of girls under 16 have experienced sexual abuse (Cawson et al., 2000) and in New Zealand it is estimated that 14% of boys and 26% of girls have experienced unwanted sexual experiences (Fleming et al., 2007). Data from the rest of world are not as clear but one study from India indicated 53% of respondents reported having faced one or more forms of sexual abuse (Ministry of Women and Child Development, Government of India, 2007). As high as these numbers are, many believe these numbers are underestimates (Freyd et al., 2005).

Data from the UN Secretary-General's Study on Violence Against Children (2006) indicate that almost 53 000 children died worldwide in 2002 as a result of homicide and up to 80–98% of children worldwide suffer physical punishment in their homes, with a third or more experiencing severe physical punishment resulting from the use of implements. In addition, 2002 data indicate that 150 million girls and 73 million boys under 18 experienced forced sexual intercourse or other forms of sexual violence during 2002 and that between 100 and 140 million girls and women in the world have undergone some form of female genital mutilation/cutting. Furthermore, in 2004, 218 million children were involved in child labor, of whom 126 million were in hazardous work, and estimates suggest that 1.8 million children were forced into prostitution and pornography. School violence (e.g., school shootings, bullying) is also not uncommon in western or Asian cultures (Chen and Astor, 2009).

There are also wars and terrorist activity causing havoc in the lives of children and families in much of the world. According to data compiled by UNICEF (2007), over the last decade 20 million children have had to flee their home because of war, with one million children orphaned or separated from family. War also contributed to the deaths of two million children with six million children being permanently disabled or seriously injured. As many as 300 000 children have been forced to be soldiers in more than 30 conflicts worldwide.

An even more common source of stress for children is grief. Studies have found that approximately 4% of American children experience the death of a parent before the age of 18 (Social Security Administration, 2000), with the number of parental deaths even higher in other countries. The death of a loved one can be one of the most severe stress-inducing events a child may encounter (Ayyahh-Abdo, 2001). Each year 7000–12 000 American children and adolescents are affected by suicide of a parent (Wilcox et al., 2010). In addition, with the death rate of children in the United States from birth to 17 being 62.4 per 100 000 (CDC, 2007), having a close friend or sibling die is not uncommon. Notably, these data do not include the number of children who experience the death of a grandparent or someone else close to them. Unfortunately, the data are clear that experiencing the death of someone close, and the resulting stress, is not uncommon in childhood.

Another source of stress in childhood is bullying. Bullying can take the form of overt or covert behaviors intended to physically harm or ostracize a particular student (Little et al., 2011a). While schools are reporting a lower rate of student bullying in the recent past, in 2005, 28% of students reported having been bullied during the last 6 months (Dinkes et al., 2007). Additionally, the last few years have seen an increase in the occurrence of cyber-bullying. There are reports of 20–40% of middle- and high-school students being bullied at least one time online (Stover, 2006).

The data are unequivocal that exposure to stress-inducing traumatic events is not uncommon in childhood and adolescence. Furthermore, this exposure appears to be increasing particularly in the areas of natural disaster, wars, and terrorism. In addition, some children experience stress in the absence of clear environmental determinants. It is the intent of the remainder of this article to discuss the psychobiology of stress, the effects of stress on development, the concept of resiliency, and approaches that adults can take to minimize adverse effects of stress in children.

Psychobiology of Stress

In the literature, the term 'stress' has been used inconsistently as either a stimulus (stressor), a response to a stimulus, or the physiological response to that stimulus (Kemeny, 2003). Kemeny also reports there are a number of factors that can influence the outcome of exposure to a stressor. These include whether the individual has perceived control over the stressor, the ambiguity of the stressor, and the level of demand placed on the individual as well as its duration and novelty. In addition, psychological stress in children might be caused by negative family circumstances such as parenting stress, experiences of negative life events, parental unemployment, or low socioeconomic status, as children can sense stress that is being experienced by their parents (Essex et al., 2002).

Stress and the resultant anxiety are natural human reactions that help an individual respond to danger or threat. When the body reacts to a stressful event, the individual experiences physical sensations like rapid heartbeat, changes in respiration, or sweaty or shaky hands and feet. These physical reactions, often called the fight–flight response, are caused by a rush of adrenaline and other stress hormones that prepare the body to make a quick retreat or 'flight' from danger. This physiological response happens instantly, but it usually takes slightly longer for the cortex to process the situation, evaluate the threat, and determine an appropriate response. When the cortex sends the all-clear signal, the fight–flight response is deactivated and the nervous system starts to calm down. Chronic or severe threat situations such as those caused by the environmental situations discussed earlier may perpetuate the physiological and cognitive response, however.

From a psychobiological perspective, the focus is on the functioning of the hypothalamic–pituitary–adrenal (HPA) axis stress–response system (Cicchetti, 2002; Sturge-Apple et al., 2012; Susman, 2006). The HPA axis serves as a primary means for organizing the body's response to environmental threat and stress. The outcome of HPA activation is the glucocorticoid (GC) hormone cortisol. This increase in cortisol levels increases cognitive processing of significant events, as well as organizing energy and physiological resources toward responding to the perceived stressor (Gunnar and Quevedo, 2007). Exposure to stressors and the resultant physiological stress response have been associated with a variety of negative health consequences including pain, sleep deficiencies, and adverse effects on the cardiovascular, endocrine, and immune systems (Maunder and Hunter, 2001; Uchino et al., 1996). For example, stress resulting from psychosocial strain in the family, has been found to be involved in the induction, or progression, of diabetes-related autoimmunity in the child during the first year of life (Sepa et al., 2005). In addition, De Bellis (2001) proposed that maltreatment in childhood and its resultant stress may be more detrimental than trauma experienced in adulthood because stress in childhood may cause delays in behavioral, cognitive, and emotional

regulation. The following section will elaborate on these developmental delays.

Stress and Development

Stress has been identified as a factor affecting both behavioral and physiological development (Bremner and Vermetten, 2001). In addition, Bremner and Vermetten report that repeated exposure to stressors early in life "has effects on stress-responsive neurobiological systems that persist throughout life" (p. 474), including dysregulation of the HPA axis. They further hypothesize that stress-induced changes in neurobiology underlie the development of psychopathology in those who do develop psychiatric symptoms.

Cohen et al. (2006a) categorize trauma symptoms into affective, behavioral, cognitive, and physical domains. Fear, depression, anger, and frequent mood changes are common affective symptoms with behavioral symptoms centering on the avoidance reminders of the traumatic experiences. Cognitive symptoms usually involve distorted cognitions the child may have about themselves, others, the event, or the world (e.g., 'the event is my fault'). There is not always a rational explanation for why bad things happen so it is common for irrational beliefs to occur. This coping mechanism appears to help the child develop a sense of control or predictability over their environment. Unfortunately, the most common irrational belief in children is blaming themselves (Cohen et al., 2006a). Physical symptoms are related to the chronic stress and can include elevated pulse rates and blood pressure, increased physical/muscle tension, and hypervigilance.

Biologically, early stress has been found to have an effect on the hippocampus, the area of the brain important in learning and memory. Neuropsychological studies in adults have shown that individuals with posttraumatic stress disorder (PTSD) have impaired attention, working memory, and learning (Vasterling et al., 2002). Studies also suggest heightened processing of trauma-related information, but weaker processing of neutral information (Karl et al., 2006). While the totality of studies with children has resulted in equivocal findings with regard to hippocampal volume, Tupler and De Bellis (2006) found that the total volume of the hippocampus was positively correlated with age and the severity of psychological symptoms of trauma. Although studies on children and adolescents have produced equivocal results with regard to hippocampal volume, biochemical studies have consistently identified an increase in urine cortisol and salivary cortisol levels in children with PTSD or abused children with PTSD symptoms (Carrion et al., 2002; De Bellis et al., 1999). Adult patients with PTSD often report a wide range of cognitive problems in memory, concentration, attention, planning, and judgment (Moradi et al., 1999). However, little such research exists with children. This led Moradi and colleagues to examine cognitive factors in children and adolescents with PTSD. Samuelson et al. (2010) found that children and adolescents diagnosed with PTSD showed poorer overall memory performance than controls, slower and less effective learning, heightened sensitivity to interference, and impaired effect of rehearsal on memory acquisition on a word list learning task.

Resiliency and Posttraumatic Growth

Not every child exposed to a traumatic stressor will develop trauma symptoms. Many children demonstrate resiliency and the ability to thrive and excel even when exposed to severe stressors (Leckman and Mayes, 2007). Posttraumatic growth (PTG) has been defined as positive psychological change experienced as a result of the struggle with highly challenging life circumstances (Tedeschi and Calhoun, 2004). It should also be noted that PTG is not simply a return to baseline after experiencing trauma, it is an experience of improvement that for some persons is significant (Tedeschi and Calhoun, 2004).

Calhoun and Tedeschi (2006) identify five domains of PTG: personal strength, new possibilities, relating to others, appreciation of life, and spiritual change. Personal strength refers to the realization people have that they may be stronger than they imagined. In other words, he/she may think, "I survived a major life challenge and I am therefore quite strong." New possibilities are defined as developing new interests, sometimes related to the trauma they experienced. For example, a child who was physically or sexually abused may become a psychologist or social worker in order to help others who have similar experiences. Relating to others refers to a greater connection to other people and increased compassion for others who may be suffering (Calhoun and Tedeschi, 2006). Especially when death or injury is part of the traumatic experience, individuals may develop a new appreciation of life and a reexamination of priorities. Finally, some individuals report deeper spiritual and existential meaning in their lives although this is more likely to happen with older adolescents and adults (Calhoun and Tedeschi, 2006).

Hefferon et al. (2009) investigated PTG and illness-related stress. They argue for the need to extend PTG research from the current five main areas mentioned earlier to include positive benefits unique to illness. They suggest a sixth area of growth: "a new awareness of the body by way of a diagnosis of life threatening physical illness" (p. 373). They report that illness-related survivors take greater responsibility for their health, engage in healthier behaviors, and reduce participation in risky behaviors. One difference they found between the respondents recovering from illness and those found in other PTG studies was that many of the respondents recovering from illness believed their circumstances to be "a gift which added value to their lives" (p. 374) while in the majority of other PTG studies, such as with bereavement, the participants would change the circumstances if it were possible.

Cryder et al. (2006) studied children who experienced Hurricane Floyd in 1999. Results indicated that there was a significant correlation between indicators of PTG and the children's competency beliefs. Although both social support and ruminative thinking correlated with positive competency beliefs, they did not correlate directly with PTG or with each other. Unlike previous research, the results of this study found that trauma severity was not associated with PTG or the other measured constructs.

Wong et al. (2009) examined the long-term effects of parental cancer in children through retrospective interviews with adults. Results indicated that 44% of participants spontaneously reported PTG when asked to describe how

their parent's illness affected their childhood. Three of Calhoun and Tedeski (2006) five areas of PTG were reported by the participants: increased appreciation for life, stronger personal relationships, and the possibility of taking new paths in life. Additionally, Wong et al. found that PTG was reported by participants regardless of whether their parent survived their illness, indicating that the threat of a parent dying may be sufficient to bring about PTG in children.

Salter and Stallard (2004) examined PTG among a population of children (aged 7–18 years) who had been involved in a road traffic accident. Results indicated that 42% of the children in the study reported some evidence of PTG following the road traffic accident although 37% were also identified as experiencing PTSD. The majority of reports of PTG came from the older children in the sample. Salter and Stallard found very limited support for positive growth in the areas of perception of self and interpersonal relationships. However, the reports from the participants did indicate an increased appreciation for life.

Alisic et al. (2008) examined the relationship between posttraumatic stress reactions, PTG, and quality of life in a large sample ($n = 1770$) of primary school children. Results indicated that posttraumatic stress reactions and PTG were positively correlated, supporting previous research which suggests that the two constructs can coexist (e.g., Salter and Stallard, 2004; Tang, 2007). There was a significant negative correlation between posttraumatic stress reactions and quality of life, and a significant but small positive correlation between PTG and quality of life.

Tang (2007) examined the prevalence and predictors of PTG among Thai adult survivors of the 2004 Southeast Asian earthquake-tsunami. Tang emphasized that worldviews in Asian cultures often significantly differ from those in western cultures and asserted that depending on one's culture, a traumatic event may indeed confirm these worldviews rather than violate them. The participants in the study were adult Thai survivors with mild physical injuries. The majority of the sample population witnessed others being seriously injured or killed, and reported friends or family members being injured, missing, or killed. Results indicated that 88% of the participants experienced varying levels of PTG and that PTG and PTSD were not mutually exclusive. Factors such as disaster-related cognitive emotional states (intrusive, hyperaroused, and avoidant states), perceived emotional familial support, and being married predicted both inter- and intrapersonal PTG. While Tang did not specifically examine children's response, clearly, cultural considerations are important.

Working with Children Experiencing Stress

While it is true that many children exposed to trauma are resilient (i.e., quickly return to prior functioning, Malchiodi et al., 2008) and others may actually improve in functioning via a process called PTG (Leckman and Mayes, 2007), many children who are exposed to traumatic experiences manifest psychological difficulties such as those described above. The development of PTSD, while differing in frequency across different trauma populations (Roberts et al., 2009), is not unusual in children and may become chronic if not addressed.

Cognitive behavioral interventions are the most common approaches used for individuals experiencing behavioral and emotional difficulties as the result of experiencing stress. A large body of research has begun to emerge on the efficacy of treatments for those exposed to severe trauma, mostly associated with abuse or exposure to an accident or disaster (Little et al., 2011b). One intervention which has been empirically supported for use with children who have experienced trauma is Trauma-Focused Cognitive Behavior Therapy (TF-CBT). While most of the research (i.e., controlled, randomized trials) has supported the efficacy of TF-CBT with sexually abused children (Cohen et al., 2004, 2005), this intervention has also proved efficacious for other types of trauma (Cohen, 2005; Cohen et al., 2006a,b). There is also a wealth of evidence to support the efficacy of TF-CBT over treatments such as nondirective play therapy and supportive therapies for children who were the victims of sexual abuse (Cohen et al., 2004). More recently, Roberts et al. (2009) conducted a meta-analysis of 25 randomized controlled trials of interventions focused on treating symptoms of PTSD within 3 months of a traumatic event occurring. Their results indicated that for individuals who displayed traumatic stress symptoms, the only significantly effective intervention was TF-CBT. The TF-CBT was particularly effective for individuals with clinical diagnoses relating to the trauma they had experienced.

TF-CBT consists of a collection of core skills that are individually based and involve activities such as relaxation training, reviewing the traumatic event via cognitive behavior therapeutic techniques and ending, usually, with some sort of permanent product (e.g., a journal). It is believed that for treatment to be effective it must be consistent with the families' religious, community, and cultural values as the therapist works closely with the family and not just with the child in isolation. A key factor in TF-CBT is restoring trust and functioning in the child and to accomplish this the therapist must model trust, empathy, and acceptance. The ultimate goal of TF-CBT is an optimally functioning individual and family and to achieve this, the therapist attempts to establish a sense of self-efficacy in the client's affect, behavior, and cognitions (Little et al., 2009).

Within the United States, TF-CBT has been demonstrated to be equally effective with both White and African American children and youths (Weiner et al., 2009). In addition, Walker et al. (2010) demonstrate the effectiveness of a model of TF-CBT that incorporates the client's preexisting religious and spiritual functioning. Internationally, TF-CBT has been used in Sri Lanka, Indonesia, and Thailand following the 2004 tsunami and in Pakistan for children affected by the 2005 earthquakes (Cohen and Mannarino, 2008). In addition, TF-CBT has been modified for use with HIV-affected sexually abused children in Zambia (Cohen and Mannarino, 2008). Other countries where TF-CBT has been successfully adapted include Palestine/Israel, the Netherlands, Germany, Norway, and Russia (National Child Traumatic Stress Network, 2008a).

Another empirically validated intervention for children experiencing trauma-related stress is Cognitive Behavioral Intervention for Trauma in Schools (CBITS), a skills-based

group intervention for children aged 10–15 (Jaycox, 2004). The focus of this intervention is on PTSD symptomatology, depression, and anxiety (National Child Traumatic Stress Network, 2008b). CBITS has been used with children who have witnessed, or been the victims of violent acts (Stein et al., 2003), been exposed to a natural disaster (Cohen et al., 2009; Jaycox et al., 2010; Walker, 2008), a house fire, or been physically injured/abused (National Child Traumatic Stress Network, 2008b). Since it was first used in the 2000–2001 school year, CBITS has been implemented widely across the United States with different cultural groups including Latinos (Kataoka et al., 2003), Native Americans (Morsette et al., 2009), and African Americans (Jaycox et al., 2010). Internationally, it has been adapted for use in Australia, China, Guyana, and Japan (SAMHSA, 2012).

CBITS involves six main components: education, relaxation training, cognitive therapy, real-life exposure, stress or trauma exposure, and social problem-solving (Jaycox, 2004). CBITS is conducted in 10 group sessions and one to three individual sessions and was designed for use specifically in schools. It also includes teacher and parent components. CBITS is activity focused with each session involving a review of activities assigned in the previous session and new activities assigned. Intervention techniques such as relaxation are also taught and practiced (Jaycox, 2004).

Conclusion

Stress, even stress that results from exposure to traumatic events is not an unusual occurrence in childhood. Unfortunately, children experience stress; be it from bullying, family crises, abuse, or a natural disaster. In fact, in a retrospective study of adults, Felitti et al. (1998) found that approximately 50% of their sample had experienced at least one stress-producing adverse event in childhood with 25% reporting having experienced two or more. Chronic stress can result in cognitive (e.g., self-blame), affective (e.g., fear, depression, anger), behavioral (e.g., avoidance, withdrawal), and physical symptoms (e.g., autonomic nervous system arousal). Deficits in learning and memory have also been reported. Biologically, this stress response is primarily due to activation of the HPA axis stress–response system and release of the GC hormone cortisol.

While many children exhibit maladaptive symptoms as the result of stress, not all children exposed to stressors go on to develop maladaptive behaviors. The fact is, many are resilient and return to baseline levels of functioning and some even experience something known as PTG and improve their psychological functioning, both without medical or psychological assistance (Roberts et al., 2009). For those children who do need assistance in dealing with stress, cognitive behavioral interventions such as TF-CBT (Cohen et al., 2006) or CBITS (Jaycox, 2004) have been empirically validated and are available.

This article is a revision of the previous edition article by M.R. Gunnar, pp. 12336–12339, © 2001, Elsevier Ltd.

Abstract

Developmental changes during infancy and early childhood guide the maturation of the hypothalamic–pituitary–adrenal (HPA) axis, and experiences during this time may program stress-responsive systems, influencing mental and physical health into adulthood. A growing body of research focuses on social, cognitive, environmental, and genetic moderators of the stress system, as well as how the HPA axis mediates physiological adaptations to stress in childhood. The effects of early stressors, including poverty, maltreatment, and neglect, are being examined to inform interventions that target children with these life histories.

The ability to mobilize behavior and physiological reactions to cope with stressors that threaten well-being is critical to survival, yet stress reactions can impair healthy development if too frequent or too long-lasting. Experiences early in life may program stress-responsive systems, affect how individuals develop, and impact lifelong health. The activity of the hypothalamic–pituitary–adrenal (HPA) system plays an important role in transducing the effects of experience on physical and psychological health (Danese and McEwen, 2012).

In this article, we will review the anatomy and physiology of the HPA system, followed by ways to measure activity of the system in infants and young children. Normative changes in HPA regulation and reactivity from infancy to early childhood will be discussed, including recent research on moderators of the HPA axis such as social relationships and child temperament. Recent studies have implicated the HPA system as a mediator of changes in brain structure and function, immune system activity, and the epigenome. In addition, there is a growing literature on the effects of severe early life stressors such as poverty, maltreatment, and neglect on the HPA axis and early child development. The extensive impact of the stress system on development will be discussed looking ahead to future research in this area.

Psychobiology of the HPA System

The majority of research on the HPA axis has been conducted using animals, which is a challenge for investigators who must translate this knowledge to studies of humans. A review of both animal and human studies of HPA axis functioning will be presented to gain a better understanding of stress system reactivity and regulation in infancy and early childhood.

The glucocorticoid (GC) cortisol is considered to be the end product of the HPA axis, produced by the adrenal cortex after the hypothalamus of the brain initiates a signaling cascade. When stimulated, the paraventricular nucleus of the hypothalamus produces corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP), neuropeptides that signal the pituitary gland of the brain to produce adrenocorticotropic hormone (ACTH). ACTH is then released into the bloodstream and travels to the cortex of the adrenal gland, where it interacts with receptors that stimulate cortisol production. Finally, cortisol is secreted into the bloodstream in order to exert effects throughout the body and to regulate HPA activity through negative feedback loops primarily in the hypothalamus, hippocampus, and medial prefrontal cortex. Additionally, CRH and ACTH participate in negative feedback loops that regulate their own production and the synthesis of peptides at other levels in the cascade.

In response to psychological stressors, the amygdala simultaneously activates the HPA axis and the sympathetic adrenomedullary (SAM) system. The SAM system is a component of the sympathetic arm of the autonomic nervous system that controls the release of epinephrine from the adrenal medulla. The release of epinephrine into the bloodstream promotes rapid physiological and behavioral responses to stressors, unlike the relatively slow-acting HPA system. Although the SAM and HPA systems act on a different timeline, they do not function in isolation. Rather, they interact in a cascade of neural events that facilitate fight-or-flight responses followed by recovery to baseline.

Following the HPA cascade, cortisol interacts with cell surface receptors to signal changes in gene transcription within the cell, which may explain the relatively long time (from minutes to hours) it takes for cortisol's actions to be measurable. The effect of cortisol varies depending on the type of receptor that is being stimulated. In the brain, two types of receptors, called mineralocorticoid receptors (MR) and glucocorticoid receptors (GR), are the targets of GCs. MRs have higher affinity for GCs than do GRs, and the balance of MR/GR occupation is imperative for HPA axis functioning. At basal levels, MRs are 80–90% occupied, while GRs are usually only occupied at the peak of the circadian rhythm or when the system is reacting to a stressor. Thus, MRs are typically responsible for basal functioning while GRs become involved to mediate functioning under conditions of stress. GRs and MRs in the hippocampus are also involved in negative feedback of the HPA axis, and the location of these receptors may explain impairment in hippocampal activities following chronic exposure to GCs. Specifically, the occupation of GRs inhibits glucose utilization in the brain, contrary to MRs, which facilitate glucose metabolism. As a result, the occupation of GRs

may have deleterious effects if stress is prolonged, and alterations in the ratio of GR/MR may increase these risks (Hostinar and Gunnar, 2012).

At basal levels, cortisol exhibits a diurnal rhythm that consists of a sharp increase at wakening with a peak 30 min later called the cortisol awakening response (CAR). After the CAR, cortisol levels decrease throughout the day, with the lowest levels 30 min after sleep onset. In addition to fluctuations due to the diurnal rhythm, cortisol shows significant increases in response to stressors that activate the HPA axis. Typically, cortisol rises sharply at the onset of a stressor, peaks 20 min after onset, and slowly decreases to baseline. However, individual variation in stress responsiveness exists in that not all individuals will activate the HPA axis in response to the same stressor, and there is considerable variability in the level of the response mounted by the system as well as the ability to return to baseline. Significant developmental changes in infancy and early childhood are discussed in detail below in relation to cortisol reactivity and the diurnal rhythm (*see* Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of).

Cortisol is not solely produced under conditions of stress, but rather it is necessary for the normal functioning of several physiological systems, including the nervous, gastrointestinal, reproductive, cardiovascular, and immune systems. McEwen (2008) explains that both hyperactivity and hypoactivity of the HPA axis have been linked to pathological functioning of the brain and other physiological systems, with alterations in basal regulation and reactivity to stressors implicated as possible mechanisms of disorder (reviewed in Hostinar and Gunnar, 2012). It is hypothesized that the relationship between stress and optimal functioning can be represented as an inverted U-curve, with too much or too little stimulation associated with lower functioning than medium-level stimulation. Animal models of chronic prenatal and postnatal stress show increases in basal glucocorticoid levels, alterations of GR/MR ratios, and increased vulnerability to stressors later in life. Cirulli et al. (2003) report that in rodent models, prolonged maternal separation as a pup is related to larger startle responses, greater freezing and anxiety behaviors, and two to three times the ACTH and GC response to stress as adults compared to those who experienced only brief separations as pups (reviewed in Hostinar and Gunnar, 2012). Increased vulnerability to stress and altered stress system activity are also seen in adults and children who have experienced childhood maltreatment, deprivation, or chronic stress.

Measurement Issues in Infants and Young Children

In children, researchers commonly measure cortisol levels using free-flowing saliva (see for review, Gunnar and Adam, 2012). Although useful, it is unfortunate that sampling higher levels of the HPA axis can only be done invasively (e.g., spinal tap for CRH or plasma for ACTH). Drugs that are used in adults to assess stress system physiology – to control for individual differences in stressor interpretation – are administered invasively and are thus not used if not medically indicated in children. Nonetheless, researchers have used saliva to sample both diurnal cortisol and cortisol reactivity to an acute stressor, although not without measurement difficulties.

Due to the diurnal rhythm of cortisol, saliva samples must be collected at the same time each day, as levels will vary greatly from morning to evening. Children often have difficulty producing enough saliva or using the passive drool method for saliva collection, which are challenges for researchers who need cortisol levels to remain unaffected by collection methods. Investigators must carefully consider the child's health, recent foods or drinks ingested, and the effects of a novel lab environment on cortisol production. The use of medication in children may alter cortisol levels or even the child's subjective experience of stress. Sufficient screening must be done to ensure all potential confounding variables are recorded. Finally, stressor paradigms intended to elicit cortisol responses may or may not be successful in children depending on age, the availability of coping resources, and the presence of threats to the social self.

Hair cortisol analysis is a relatively new method of sampling that aims to measure long-term cortisol exposure as opposed to real-time fluctuations in cortisol levels captured by saliva. Each 1 cm length of hair represents approximately 1 month of development, and thus cumulative cortisol measurements can be obtained for specific time periods. Further research on hair cortisol analysis must be conducted to verify its routine use in samples experiencing chronic stress.

Developmental Changes in the HPA Axis

Newborns have the capacity to mount physiologically significant cortisol and ACTH responses to environmental stressors. Specifically, stressors that elicit pain, such as heel lances, promote sensitization to the response while handling stressors, such as physical examinations, show habituation over time. Although newborns show robust cortisol responses to even mild stressors, across the first year of life it becomes increasingly difficult to elicit cortisol responses to the same types of stressors. This period of hyporesponsiveness mimics the stress hyporesponsive period that researchers have studied in rat pups between 4 and 14 days of age, and it is uncertain whether infants enter the functional equivalent of this period during the first year of life. By 1 year of age, infants typically show no increases in cortisol to stressors such as separations or stranger approach, even while exhibiting significant behavioral distress (Hostinar and Gunnar, 2012). Research suggests that physiological changes including improved negative feedback regulation of the HPA axis and decreased adrenocortical sensitivity to ACTH, may at least partially explain hyporesponsiveness of the system during this period. Relationships with caregivers also act as an important moderator of the HPA response. Children who experience supportive adult care are better able to buffer cortisol responses, while children who have been separated from their caregiver exhibit elevations in cortisol to the same stressors. Over time, children develop the ability to regulate HPA responses in the absence of caregivers. Although able to mount a significant cortisol response, newborns lack the typical diurnal cortisol rhythm seen in adults and instead show two peaks that are 12 h apart and do not depend on the time of day. By 3 months of age, infants usually develop a more adult-like rhythm that includes high morning and

low evening cortisol levels. Watamura et al. (2004), reviewed in Hostinar and Gunnar (2012), report that napping in toddlers seems to facilitate decreases in cortisol across the day, possibly involving development of the circadian HPA axis rhythm through age 3.

Levels of corticosteroid-binding globulin (CBG), a factor that binds circulating cortisol and renders it biologically inactive, may explain differences in cortisol levels across early childhood. In adults, about 80% of cortisol is bound to CBG, but CBG levels are low in newborns, and adult levels are not reached until approximately 6 months of age. Thus, although total plasma cortisol is low in newborns, levels of free cortisol in infants under 6 months often surpass older infants and children because of increasing cortisol levels and low levels of CBG. Young infants also show marked increases in free cortisol to very minor stressors such as undressing. Remarkably, the HPA axis is relatively mature by 6 months of age (Hostinar and Gunnar, 2012).

Relationships as Regulators of the HPA System

Until approximately 6 months of age, the infant HPA axis reacts robustly to a variety of stressors, but between 6 and 12 months of age, cortisol responses are mediated by caregiver interactions. Children's attachment to caregivers is an important moderator of physiological reactivity. In the presence of a caregiver, toddlers with a secure attachment to the caregiver have a buffered cortisol response to stressors, while those with insecure attachments show elevations in cortisol (Hostinar and Gunnar, 2012). Ahnert and colleagues (2004) report that attachment to caregivers does not predict the magnitude of the cortisol response during daily separations such as day care, but securely attached children are more likely to show increased cortisol responses that match their level of behavioral distress (reviewed in Hostinar and Gunnar, 2012). Further, Luijk et al. (2010) found that children who have disorganized attachment to caregivers – often observed for children whose caregivers are depressed or abusive – exhibit elevations in cortisol and a more flattened diurnal cortisol pattern than children with non-disorganized attachment (reviewed in Hostinar and Gunnar, 2012). A history of responsive care also predicts whether cortisol will be buffered in response to stress, as responsive caregiving is thought to give children an outlet to express emotions without triggering the neuroendocrine response (Hostinar and Gunnar, 2012).

Social stressors within the family such as child conflict and interparental violence are associated with altered HPA axis reactivity and regulation in children. Infants at 7 months who experienced more home violence and used less caregiver-oriented regulation strategies were more likely to show high cortisol reactivity (Towe-Goodman et al., 2012). However, there is evidence that by toddlerhood, children who experience more violence and maternal unavailability actually show lower cortisol reactivity to a social stressor (Sturge-Apple et al., 2012). Consistent with hyporeactivity observed in toddlers, 4–5-year olds who experienced greater child conflict in the home had lower morning cortisol and flatter diurnal cortisol rhythms than children who experienced less conflict (Slatcher and Robles, 2012).

A more normative but less potent social stressor for children is the transition to child care, which involves peer interaction and separation from primary caregivers. A meta-analysis by Vermeer and van IJzendoorn (2006) found that while most infants and toddlers show expected decreases in cortisol across the day at home, many children at day care actually show increases from morning to afternoon (reviewed in Phillips et al., 2011). Ouellet-Morin and colleagues (2010) report that by 3 years of age, children are more likely to show decreases at both home and day care, especially if they have more day care experience (reviewed in Phillips et al., 2011). Sensitive and responsive caregiving from both the primary caregiver and day care staff helps children to adapt effectively. Separation from the caregiver is less likely to activate the HPA axis if high-quality substitute care is provided. Attachment security to the teacher predicts falling cortisol levels across the day, and a secure attachment to the caregiver interacts with day care quality so that those with better-quality care have buffered cortisol levels (Badanes et al., 2012). In addition, peer relations are a source of significant stress in day care, and child social competence is a skill that reduces stressful interactions with peers and lowers cortisol production as a result (Hostinar and Gunnar, 2012).

Temperament

Behavioral inhibition in young children has been consistently linked to increased physiological reactivity, including greater activity of the HPA axis. Behavioral inhibition parallels the activation of conditioned and unconditioned fear circuits in the brain, which influence behavioral responses as well as autonomic and HPA axis reactivity. However, HPA axis activity may not necessarily be a reflection of fear-related responses but rather the child's ability to cope with a stressful situation. For example, children who are behaviorally inhibited may avoid social situations that would trigger an increase in cortisol, but in situations that they must confront, cortisol reactivity may indicate whether children are coping successfully. The presence of a caregiver to whom the child is securely attached may help the child to cope and thus explain why some studies do not report higher cortisol in behaviorally inhibited children.

Children who are behaviorally inhibited or have negative emotional temperaments may be more susceptible to high HPA reactivity under conditions of low-quality care than children with more moderate temperaments (Phillips et al., 2011). Important gender differences may exist in the components of temperament associated with cortisol reactivity. Gunnar et al. (2010) report that in 3–4-year-old girls, those who exhibited more anxious and vigilant behavior were more likely to show a rise in cortisol across the day at day care. For boys, however, this rise was related to angry, aggressive behavior (reviewed in Phillips et al., 2011).

In a peer context, children from generally low-risk backgrounds who are rejected by others show higher cortisol levels. Gunnar et al. (2003) report that preschoolers who are overly controlled and less exuberant are more likely to have high cortisol levels, but in a social situation, it is the less controlled (more impulsive) and more exuberant children who are more likely to be rejected by peers and show higher cortisol levels as

a result (reviewed in Hostinar and Gunnar, 2012). Although cortisol levels for average or exuberant preschoolers lessen over time, highly inhibited children do not show this decrease on average. A recent study found that inhibited children who were more dominant and popular than other inhibited children showed increases in cortisol over time. On the other hand, exuberant children who were not socially integrated showed consistently high cortisol levels across the year (Tarullo et al., 2011). Gunnar et al. (2011) report that behavioral inhibition may also moderate the effect of cortisol reactivity on later internalizing symptoms, with preschoolers who are highly inhibited and reactive at the greatest risk for internalizing symptoms (reviewed in Phillips et al., 2011).

Effortful control is a higher order dimension of temperament that includes the ability to focus attention and inhibit a prepotent response. Effortful control has been identified as an important moderator of the relationship between negative emotionality and behavior in children. Children who score highly on measures of effortful control are better able to suppress both positive and negative emotions. In general, preschoolers who exhibit more effortful control show better regulation and less activation of the HPA axis as well as a more adult-like diurnal cortisol rhythm.

Moderators of Stress System Reactivity and Gene Expression

Individual differences in child cognitive and emotional factors explain significant variation in HPA axis activity. Specifically, executive function, the top-down ability to manage lower order cognitive processes, has been shown to moderate cortisol levels. Blair and colleagues (2011) found that infants and toddlers with higher cortisol levels tend to have lower levels of executive function in early childhood, and cortisol partially mediates the positive effect of parenting on executive function (reviewed in Blair, 2010). In addition, Blair et al. (2005) reported that the ability to mount a moderate cortisol increase to challenge and appropriate return to baseline is positively associated with executive function and teacher-reported self-regulation (reviewed in Blair, 2010). The child's ability to regulate emotion is another important moderator of HPA activity. As children gain emotion regulation skills, they also become better at regulating physiological reactivity to psychosocial stressors. Good emotion regulation skills, including the ability to utilize appropriate coping strategies, have been shown to buffer cortisol responses to social stress in preschoolers.

Unfortunately, child cognitive and emotional factors may not be enough to protect children from stress system dysregulation in response to unfavorable home environments. Essex et al. (2002), as reviewed in Hostinar and Gunnar (2012), report that maternal depression, a condition that significantly disrupts family life and maternal care, is related to elevated cortisol levels and heightened HPA axis reactivity in early childhood. Maternal comorbid anxiety and depression has also been linked to increased infant cortisol reactivity. More studies are needed to understand how specific types of parental psychopathology, as well as the timing and treatment of disorders, affect child stress reactivity and regulation.

Gene–environment interactions explain at least part of the variance in stress regulation and responsiveness in children. A study of 19-month-old twins aimed to understand the unique contributions of genes and the environment to differences in stress reactivity under differing levels of adversity (Ouellet-Morin et al., 2008). In addition to unique environmental influences, under conditions of low familial adversity, shared genetic influences most strongly affect cortisol responses, while under conditions of high familial adversity, shared environmental influences showed greater associations with cortisol responsiveness. As a result, experiences in early childhood may have a powerful programming effect on the stress system in highly stressful conditions.

Allelic variation in genes that influence the HPA axis and related systems (e.g., the sympathetic nervous system) operate through various mechanisms to influence development. These interactions between the gene and the environment may operate differently in conditions of stress versus basal functioning, and multiple genes likely interact with each other simultaneously to influence protein synthesis and processes that affect downstream behavior. The ability of genes to influence behavior may differ depending on the timing during development. For instance, the activity of a gene during a sensitive period could have greater implications for development than during another period. Alterations to the genome itself may occur in response to a particular environment, including methylation of specific functional genes and shortening of DNA telomeres. Oberlander and colleagues (2008) report that maternal depressed/anxious mood in the third trimester predicted specific methylation of the *NR3C1* gene, which was then associated with an increased cortisol response in infants at 3 months (reviewed in Miller et al., 2011). Drury et al. (2011) noted telomere shortening in 4-year olds who had spent most of their lives in institutions, showing the impact of stress even in early childhood (reviewed in Danese and McEwen, 2012). Studies that integrate measurement of the environment, changes to the genome, and subsequent physiological alterations will be essential to understanding the mechanisms by which the environment and the genome interact to affect individual development.

HPA System Impacts the Brain and Immune System

Interactions between the environment and the HPA axis produce further alterations in the brain, the immune system, and the epigenome, among other physiological systems. Research in animals has begun to elucidate the mechanisms behind these changes, so most of what is known about stress, the HPA axis, and other physiological systems has been extrapolated from animal research. However, studies in infants and young children are emerging that allow us to understand how these mechanisms might be operating early in human development.

The HPA axis provides a way in which stress can shape brain development. Cortisol passes through the blood–brain barrier, and brain regions such as the hippocampus and amygdala are dense with glucocorticoid receptors. Although moderate levels

and brief increases in cortisol appear to enhance brain function, frequent or chronically high levels of cortisol may produce cell death in addition to other functional or structural changes in the brain. In maltreated (highly stressed) children, the most consistent neurological finding is impairment in the prefrontal cortex (PFC). The PFC tends to be smaller in volume, and children are more likely to experience impulsiveness, inattention, and deficits in executive function (Danese and McEwen, 2012). Many – but not all – studies report increased amygdala volume in maltreated children, but there is little evidence to date of changes in hippocampal volume. The animal literature suggests that HPA axis hyperactivity is a plausible mechanism by which neurological deficits arise.

Stress and elevated cortisol levels in early childhood have been linked to immune system impairments including decreased antibody levels and increased inflammation. Watamura et al. (2010) found that children whose cortisol increased across the day at child care tended to have lower antibody levels at home, and children with higher home cortisol were more likely to experience parent-reported illness (reviewed in Vermeer et al., 2012). In addition, children in both the home and at child care showed lower antibody levels when caregiver sensitivity was low (Vermeer et al., 2012). Unlike the decreases observed in antibody levels, stress in early childhood has been linked to increased levels of inflammatory proteins. This elevation could be due to excessive stimulation of the sympathetic nervous system and impairments in HPA axis signaling, but it is possible that stress is not increasing inflammation but rather the effect is the reverse; inflammation is increasing glucocorticoid levels (Danese and McEwen, 2012). Thus longitudinal work is needed to understand the direction of effects.

Early Adversity: Poverty, Neglect, and Maltreatment

Early adversity significantly impacts stress system regulation, gene expression, and a myriad of other developmental processes from prenatal to adult life. Significant adversity consistently produces stress system disruptions in infants and young children (Danese and McEwen, 2012). Chronic stress has been linked to alterations in HPA axis functioning, but the patterns of disruption vary based on the type, timing, and subjective meaning of the stressor. Such variation is to be expected. When the HPA axis is activated frequently for prolonged periods, it undergoes remodeling that results in normal to low levels of cortisol production in reaction to brain signals of threat. At the same time, chronic threat increases the activity of brain circuits that process threat, including increasing the production of CRH from sites such as the central nucleus of the amygdala. The result is hypocortisol production in the face of heightened sympathetic and central brain stress signals (as reviewed in Hostinar and Gunnar, 2012). For the researcher measuring cortisol, however, the result is sometimes finding elevated and sometimes finding suppressed cortisol activity in response to adverse life conditions in children. For example, Chen et al. (2010) report an association between low socioeconomic status (SES) and greater increases in diurnal cortisol from birth to age 2, and the effect was partially mediated by increased perception of threat and family chaos in low SES children (reviewed in Miller et al., 2011). By preschool, children in poverty have been shown to exhibit blunted morning cortisol levels and a flattened diurnal slope (Zalewski et al., 2012). This pattern could be a continuation of the increased cortisol output shown from birth for low SES children, putting children at risk for the deleterious effects associated with chronic activation of stress systems.

Children in foster care show a similar pattern of stress system dysregulation to children living in poverty, with lower morning cortisol levels and a flatter slope across the day. Dozier and colleagues (2006), as reviewed in Hostinar and Gunnar (2012), report that children between the ages of one and five living in foster care are more likely to show atypical diurnal cortisol patterns (high or low) than children not living in foster care. Morning cortisol in foster children may signal types of maltreatment the child has experienced. Bruce et al. (2009) found low morning cortisol to be related to higher incidence of severe physical neglect in preschool-age foster children, and high morning cortisol was linked to severe emotional maltreatment (reviewed in Hostinar and Gunnar, 2012).

Although there are few studies of cortisol regulation and reactivity in infants and young children who have experienced maltreatment, there is evidence that poor early care affects neuroendocrine levels early in life (Hostinar and Gunnar, 2012). Specifically, maltreated preschoolers may exhibit lower cortisol reactivity to stress than children who are not maltreated, and on days of high conflict they may produce even lower cortisol levels. This hypoactivity could be due to down-regulation following periods of high GC levels after repeated exposure to maltreatment. Bugental et al. (2003) report that less severe forms of maltreatment, such as maternal emotional withdrawal, have been related to elevated baseline cortisol levels, and increased cortisol reactivity has been noted in infants who receive frequent corporal punishment (reviewed in Sturge-Apple et al., 2012). Increases in cortisol may result when infants have limited use of their attachment figure to help them buffer stressors such as maltreatment. Excess glucocorticoid levels in maltreated children may be particularly harmful if they affect the developing brain, especially neural circuits involved in interpreting threats and regulating the stress response (Danese and McEwen, 2012). It is likely that HPA hyperactivity is adaptive during the short-term response to stress, but these effects may no longer be adaptive when the response is prolonged or once the child is removed from the context of maltreatment.

Early social deprivation has been shown to significantly alter HPA axis function. Toddlers living in institutions with poor quality care typically show blunted morning cortisol levels and little to no decrease in cortisol across the day. Children may also have impaired HPA axis regulation in social situations even after adoption into a supportive home. Post-institutionalized children who had been with their adoptive families for at least 3 years showed prolonged cortisol elevations during an interaction with their mother, but not a stranger. Further, children who experienced more severe neglect and deprivation are more likely to exhibit dysregulation of the HPA axis years following rescue (as reviewed in Hostinar

and Gunnar, 2012). Current research is being done to examine recovery of the HPA axis activity following the transition from early deprivation to more optimal care in post-institutionalized children.

Lasting Effects of Early Adversity

Recent evidence strongly suggests that psychosocial stress and altered HPA activity during the first few years of life have the potential to impact physiological systems, cognition, and behavior across the lifespan. In a sample of adults who were separated from their parents as children during World War II, those who experienced separation had higher baseline cortisol and ACTH levels as well as greater cortisol reactivity than nonseparated adults (Pesonen et al., 2010). The effects were greatest for children separated during early childhood compared to infancy or school-age separations. Trauma during early childhood has also been linked to alterations in adult physiological systems that are sometimes inconsistent with those reported in childhood. For instance, although the amygdala seems to be enlarged in maltreated children, adults who experienced maltreatment as children have normal to decreased amygdala volumes (Danese and McEwen, 2012). In addition, adults maltreated as children show decreased hippocampal volume, although there were no differences between maltreatment groups in hippocampal size in childhood. Abnormalities in brain regions following childhood stress could be the result of excess glucocorticoid or inflammatory protein exposure over time. These findings underscore the importance of studying effects of early childhood stress and altered HPA activity developmentally because mechanisms that produce certain outcomes in childhood may result in different outcomes later in life.

Future of Research

A proliferation of research using human models of early stress has occurred during the past decade, but future psychobiological studies are needed to further elucidate the mechanisms of normative and atypical development in children. Both animal and human researches will be necessary to understand the interactions between the HPA axis, immune system, genome, and the brain. In addition, further studies of social, cognitive, and environmental moderators of stress system reactivity will help researchers understand how early experiences affect later mental and physical health. Recent interventions have successfully targeted the stress system as a mediator of recovery from early adversity, and future applied work will be necessary to understand how these mechanisms operate and how to apply scientific knowledge to help children in need.

Abstract

Psychological stress is a popular term denoting processes believed to contribute to the onset and maintenance of a variety of mental and physical conditions. Despite widespread interest in psychological stress and its consequences for health and well-being, debate remains about how to best define the term. Three perspectives for defining and studying psychological stress are reviewed with respect to their history, development, and current status. These three perspectives on psychological stress differ in terms of the relative emphasis each places on the environment, the organism, and the interaction between the organism and environment over time. Conceptual and methodological considerations and implications of the three perspectives are reviewed. Recent elaborations of the concept of stress that attempt to expand its biological consequences over time are also discussed. Finally, promising topics for future inquiry on psychological stress are addressed.

Psychological stress, like the general term 'stress,' is a commonly used expression that defies a universally agreed-upon meaning. These definitional challenges are not due to a lack of interest in the concept of psychological stress. Indeed, the opposite is the case. Stress is a concept that fascinates scientists, clinicians, and laypersons alike, for its apparent ability to explain a wide-range of conditions and adverse outcomes. From understanding immediate emotional states through understanding a variety of mental and physical disorders, stress is a commonly invoked cause. It is the resulting complexity of this broad explanatory enterprise that both attracts and vexes scientific investigators.

To understand current thinking about psychological stress, historical considerations are addressed first in the following section. Subsequently, the three different perspectives that have evolved to define stress are described, along with their own conceptual and methodological traditions for operationalizing psychological stress and conducting research on its effects. Following this, key conceptual and methodological issues regarding psychological stress are presented. We conclude with a discussion of contemporary trends and future directions regarding psychological stress.

Historical Considerations and Concerns

Curiosity about the implications of emotions for health is age-old, dating back to the origins of holistic approaches to medicine as exemplified by the writings of Hippocrates (400 BC). Interest in the influence of psychological factors on emotional functioning has consequently represented a related theme of interest over the centuries (*see* Environmental Stress and Health). The basic premise is that stress gives rise to distressing emotions, which in turn are associated with perturbations in biological systems, which in turn contribute to disease onset or exacerbation. Yet the connections between various related terms and their intended ideas are quite rich, and more complex than the current vocabulary suggests. Indeed, 'stress' is derived as a shortened form of 'distress'; disease, in turn, originally referred to 'dis-ease,' or distress (Rees, 1976). It is in this lexicographic context that the varied connections between stress, distress, and disease can be appreciated, only some of which may be useful for scientific purposes.

As rich in explanatory power as psychological stress might be for understanding the causes of distress and disease, the linguistic overlap and interplay of these terms also raises problems. The intuitive appeal of these ideas, terms, and relations can foster false theories and findings. There is a tendency to 'explain away' disorders of unknown etiology based on prevailing beliefs about the unwanted or adverse social or psychological circumstances (Monroe, 2008). For example, before the physical causes of specific infectious diseases were discovered, the origins of these illnesses were commonly ascribed to psychological stress and distressing emotions (Sontag, 1978). Prior to the discovery of the *Treponema pallidum* spirochete, the common and deadly mental condition of general paresis (or tertiary syphilis) in the nineteenth century commonly was attributed to the 'demands of civilization on physical and mental powers,' including 'overwork,' 'overstudy,' 'competition,' and the 'feverish pursuit of wealth and social position' (Kellogg, 1897). In contemporary parlance, psychological stress frequently provides a satisfying pseudoexplanation for poorly understood mental and medical conditions. Whether it is in the scientific journals, the popular media, or the physician's office, 'stress' is often resorted to for explaining mystifying maladies and miseries. The intuitive appeal of explanations based on psychological stress and related ideas require firm thinking and sound science to differentiate valid associations from plausible and convenient fictions.

Research Traditions and Major Definitional Perspectives

Two research traditions can be discerned which, together, have given rise to three definitional perspectives on psychological stress. The first research tradition derives from clinical observations and field studies of humans exposed to threatening and adverse circumstances. The second tradition arises from animal

laboratory studies, where experimental control over stressful conditions and response alternatives of the organism has been employed. Emerging from and uniting these two traditions is the general interest in the psychological concomitants and sequelae associated with adverse environments and stimuli, particularly with regard to their implications for subsequent health and well-being. How this general interest in environment, responses, and disorder has been more precisely conceptualized and defined, though, has resulted in three differing definitional perspectives on defining stress. The differences between these perspectives, as explained next, revolve around the relative emphasis placed on the environment, organism, or environment–organism interactions over time as the focal feature for defining and operationalizing psychological stress.

The Stimulus or Environmental Perspective

The stimulus or environment perspective adopts the position that psychological stress derives from the characteristics of the environment the person or organism confronts. The underlying assumption is that objective external circumstances can be conceptualized and defined as psychologically demanding, threatening, benign, and so forth. Prior research on both humans and animals has advanced understanding of this perspective. In human field or human laboratory research, the stimulus conditions were recorded in naturalistic contexts or manipulated in ethically responsible ways. Animal laboratory research, on the other hand, allowed for experimental control over the environmental conditions, thereby providing opportunities for greater latitude in exposure to diverse challenging and threatening stimuli.

Other factors, too, were influential in promoting the environmental perspective. Attention to the environment for creating stress and illness became especially evident toward the mid-twentieth century; the experiences of World War II reshaped the ways in which a breakdown in human functioning was viewed. Prior to this time, it was thought that individual vulnerability (i.e., biological) largely accounted for who succumbed to stress. Normal people were believed to maintain health and survive the ravages of stress; the biologically predisposed or tainted were those who broke down. With the awareness that one-third of American casualties in World War II sustained no physical injury (Weiner, 1992), the idea that severe stress could precipitate psychological and physical breakdown in previously normal individuals was incorporated into medical and psychiatric thinking (Dohrenwend, 1998). This brought to the foreground the importance of extreme and challenging environments for the defining psychological stress and for investigating its health consequences in normal as well as vulnerable populations.

Finally, a surge of popular interest and research activity in psychological stress from the environmental perspective came from another avenue of inquiry: life events questionnaires. Thomas Holmes and Richard Rahe promoted the idea that life stress could be defined and assessed in an objective manner through surveying people's recent experiences. These researchers developed a list of life events observed to occur prior to the onset of disease, including items such as marriage, trouble with the boss, change in sleeping habits, death in the family, and vacation. They named the list of 43 life events as the Schedule of Recent Experiences (SRE). The events on the SRE subsequently were collated and weighted using psychophysics procedures, producing the Social Readjustment Rating Scale (SRRS; Holmes and Rahe, 1967). Literally thousands of studies have been conducted with the SRE, SRRS, and the proliferation of derivative life event checklists they spawned (Monroe, 2008).

The Response Perspective

From the response perspective, psychological stress is viewed as the complex of *reactions* of the organism to the adaptive demands imposed by environment change and challenge. This perspective can be traced to the writings of Darwin and the theory of natural selection. It is in these ideas that attention began to shift toward the *implications* for the organism of the dangers and threat associated with environmental demands, bringing to light an awareness of the importance of the ongoing *adaptations* of the organism to the everaltering external circumstances. The response approach to defining stress takes on special importance from this evolutionary vantage point, as it recognizes that not only biological and behavioral repertoires are needed for enhanced fitness and adaptive capacities. Most importantly from a psychological perspective on stress, evolution also fostered skills in *anticipation* of dangers and adversity (Weiner, 1992). In other words, the ability to not just respond to environmental exigencies, but to anticipate and to prepare for such potential exigencies, provided a more complete and effective adaptive system. Being able to foresee, prepare for, and prevent potential problems in the future drew upon mental, emotional, and behavioral repertoires that, over time, enhanced survival and reproduction.

The twentieth century brought more sustained and intense interest in psychological stress from the response perspective. Claude Bernard's attention to the body's regulatory functions and homeostasis, along with the physiological regulation of emotions by Walter Cannon, furthered scientific interests in how the body maintained its regulatory functions in the face of changing external circumstances. Most importantly, Hans Selye introduced the term 'stress' into formal scientific arenas. By defining stress as "the nonspecific response to the body of any demand made upon it" (Selye, 1976: p. 74), Selye grounded the concept explicitly in the response of the organism to environmental challenge. (He reserved the term 'stressor' to denote the stimuli or environmental conditions eliciting stress responses.) Widely regarded as the father of modern stress theory and research, Selye and his writings on the stress response essentially launched the field and contributed greatly to the appeal of the stress concept to both researchers and laypersons alike.

The Environment–Organism Transaction Perspective

The stimulus and response perspectives on psychological stress each possess advantages, yet they also have important limitations. For example, the objective characteristics of the environment do not always predict the organism's responses with precision; individual differences in response to identical or similar stimuli are common. Moreover, when considering the

response perspective, there are many levels of response (e.g., psychological, behavioral, biological) and numerous potential response indicators within these levels (e.g., specific emotions, behaviors, psychophysiologic, or hormonal reactions) to draw upon, many of which display different patterns of relationships with distinct environmental challenges (Weiner, 1992).

To address these limitations and enlarge the scope of inquiry, psychological stress has been proposed to represent a particular *relationship over time* between the organism and environment. This third perspective holds that psychological stress is the product of the individual's ongoing transactions with ambient circumstances, particularly circumstances that are perceived as taxing or exceeding adaptive resources. Several possibilities are entertained within this perspective, ranging from an emphasis on stressful *experiences* (Weiner, 1992) through emphases upon the ongoing process of event occurrence, appraisal, coping, reappraisal, and eventual resolution (Lazarus and Folkman, 1984). For instance, a person is faced with the threat of job loss. This individual appraises the degree of threat in relation to his or her personal circumstances (e.g., economic conditions, ability to find alternative employment, possible embarrassment). He or she undertakes measures to cope with the possible termination of employment (e.g., works harder, begins looking for alternative work). As a result of these efforts, the environmental conditions are changed, hopefully for the better (but not necessarily) and the resulting responses altered as well. The core feature of this perspective is an *active process* between a dynamic environment and an adapting organism over time, whereby stress is the accruing and collective net result of the process.

Conceptual Challenges and Problems

After the 1950s, stress became a common term, appearing across diverse research literature in sociology, psychology, medicine, physiology, and biology. A broad array of loosely related constructs was united under this common rubric. At least two issues arise from this explosive growth in research on stress: (1) individual differences; and (2) generality versus specificity of psychological stress.

Individual Differences

Despite the promising leads of early research on psychological stress, it became apparent that variability in people's responses to stressful circumstances was common. Not all individuals succumb to even the most extreme of situations, while some people break down in the face of apparently minimal demands. Theory and research were needed to account for such variation across individuals, thereby introducing factors hypothesized to moderate stress effects.

A multitude of factors has been proposed as potential stress moderators. Attention to this issue has focused on individual difference variables such as appraisal of threat and coping (Lazarus, 2000; Monroe, 2008), and a variety of other considerations believed to moderate the effects of stress (e.g., social support; Brown and Harris, 1989; Holt-Lunstad et al., 2010). The net effect has been to broaden the conceptual arena and research operations considerably. Multifactorial models have been introduced taking into account a range of factors that could influence stressful features of the environment and responses over time (*see* Coping across the Lifespan).

Generality versus Specificity of Psychological Stress

A second issue related to the rapid growth of stress research pertains to the omnibus nature of stress. On the one hand, the stress concept has united a variety of cognate constructs and emphasized the general nature of the stress response with regard to a wide variety of adaptive demands (e.g., Selye, 1976). On the other hand, the unique implications of specific environmental challenges and the distinctive responses they may elicit could be obscured within such a general viewpoint (e.g., Weiner, 1992). Research from both the animal laboratory and human field studies suggests that responses to stressors can be relatively specific with respect to the particular the demands imposed, and recognition of such specificity may be key for further understanding many of the adaptive and maladaptive implications (Dohrenwend, 1998; Weiner, 1992; *see* Stress, Neural Basis of)

Overall, the challenge for research on psychological stress has been to remain true to its roots in extracting the 'essence' of psychological phenomena related to adversity, while at the same time not becoming so overly inclusive as to become essentially meaningless or to obscure attention to other more specific associations. Such an agenda raises important methodological issues, as discussed next.

Methodological Considerations

Measuring psychological stress in a reliable and valid manner has been a continuing challenge for stress researchers. For example, animal laboratory research has proven useful for more precise specification of both stimulus parameters and response characteristics associated with psychological stress. Yet the methods adopted for such research in the past often constrained the array of possible responses the animal could make, creating unnatural environmental conditions. For instance, early studies on stress commonly subjected animals to extreme stressors that were not representative of the kinds of challenges the animals would typically face (e.g., electric shocks). Furthermore, the animals were not able to respond in ways that they typically would in the wild (e.g., fight or flee). These artificial paradigms in turn could yield misleading information and views about how adaptation proceeds under more ecologically valid conditions (Weiner, 1992; *see* Measurement of Stress).

In terms of human field research, there has been considerable and ongoing debate about measurement procedures for assessing stressful life events. Research on self-report life event checklists, such as the SRE, has revealed serious psychometric limitations (Monroe, 2008). A major concern with self-report life event checklists is the problem of intracategory variability (Dohrenwend, 2006). This refers to the inconsistencies in how respondents interpret and respond any particular life event item on such checklists. For example, one person might interpret the event of 'Serious illness of a close family member' being fulfilled if his or her child had a case of the flu, another if

a distant relative had a heart attack, and finally another if a first-degree family member had a stroke. In this example, the myriad ways in which a person might interpret 'serious' and 'close' leads to an unacceptably large range of response alternatives. Many if not most listed items can produce such undesired and uncontrolled variation. The use of naïve research designs with self-report checklists, too, frequently has led to spurious findings. For example, a depressed person actually may cause some life events to occur, such as 'trouble at work,' and 'difficulties with spouse.' This means that instead of the life event stress causing depression, the reverse is true: The depression causes the life event. Furthermore, many of the life events on the SRE and similar checklists are direct indicators of psychological disorder or illness (i.e., 'major change in eating habits, major change in sleeping habits'). This means that if the study relies only upon the self-report checklist completed by the study participant, the resulting measure of stress will be confounded with disorder and thereby of little scientific value. Although more refined and comprehensive self-report measures have been developed in an attempt to address such concerns, fundamental problems with this particular methodology remain (Dohrenwend, 2006; Monroe, 2008).

In response to these measurement concerns about self-report life event checklists, other stress researchers have developed semi-structured interviews. These interview-based measures provide detailed inquiry into the lives of the participants, and adopt explicit guidelines, decision rules, and operational criteria for defining and rating life events (Brown and Harris, 1989; Dohrenwend, 2006). In general, utilizing these procedures enhances the reliability of life event assessments and provides better prediction of outcomes. Although these approaches are more time and labor intensive, they represent among the best available tools for measuring psychological stressors. Importantly, too, these approaches provide flexibility in measuring life stress, allowing for ratings of specific dimensions of stress (e.g., loss, threat, danger, humiliation) and for taking into account the influences of moderators of stress impact. Thus, in theory, such approaches can help to bridge the gap between a strictly stimulus perspective, and to incorporate useful features of the response and organism–environment interaction perspectives (Monroe, 2008).

Recent Advances and Future Directions

Over recent times it has become increasingly evident that life stress and other psychosocial factors influence susceptibility to a variety of mental and medical conditions (Cohen et al., 2007). This emerging consensus has directed the field toward identification of the behavioral and biological mechanisms via which stress influences disease susceptibility. Broadly speaking, these collective research activities have produced a wealth of research findings substantiating how stress impacts neuroendocrine, immunologic, and genetic dynamics in ways that, in theory, can lead to illness. These avenues of investigation hold considerable promise for future research addressing the central question of how environmental adversity 'gets under the skin' (Miller et al., 2009). We point to three emerging areas of interest that will likely be of importance over the coming years.

One conceptual development that has been part of these recent advances is a shift in thinking about the nature of stress and its effects on major biological regulatory systems of the body. The concept of *allostasis* has been advanced to take into account how the organism achieves stable biological functioning over time despite ongoing adaptive challenges and change. Allostasis enlarges theoretical attention to take into account a broader range of whole-organism regulatory mechanisms that are recruited in adaptation to constantly changing environmental circumstances. The cumulative burden on the body's major regulatory systems of repeated or poorly controlled allostatic activation over time is referred to as *allostatic load*. In other words, allostatic load represents the cumulative 'wear and tear' on the major body systems resulting from either too much stress or from poor regulatory management of stress, and is thought to be a key part of the process that results in vulnerability to disorder and disease. Allostasis and allostatic load have figured prominently in recent research neuroendocrine and immune mechanisms involving a wide range of conditions, but especially coronary heart disease, obesity, diabetes, and the metabolic syndrome (McEwen and Wingfield, 2003; Monroe, 2008).

A second significant trend over the past decade has been the integration of psychological stress and genetic information in relation to health and well-being. With the completion of the human genome project in 2003, the aspiration to study gene-by-environment interactions in relation to health and disease became readily feasible and fashionable. Psychological stress, as a key conceptual bridge linking variation in environmental adversity with gene function, has been a core construct in much of this research. A landmark article by Caspi et al. (2003) reported that individuals with one or two short alleles of the serotonin transporter gene promoter polymorphism (5-HTTLPR) particularly were susceptible to depression if they have been exposed to adversity early in life or to recent stressful life events. The Caspi et al. (2003) findings have helped to spawn a new era of research on life stress and genetic predisposition (i.e., gene-by-environment interactions) in relation to a wide variety of psychological and physical conditions. One very important lesson learned from this rapidly developing literature is that care must be taken to appropriately define and measure life stress if the hypothetical interactions with genetic vulnerability are to be detected reliably (Monroe and Reid, 2008; Uher and McGuffin, 2010).

Finally, the conceptual developments involving allostasis and the attention to gene-by-environment interactions point to the potential importance of greater specificity in thinking about, and assessment of, psychological stress in future research. For instance, early childhood adversity is well recognized as an important risk factor for a wide array of medical and mental problems later in life. How early adversity impacts development, particularly with regard to allostatic load and ongoing psychological stress, may be a key topic for understanding how psychological stress can influence disease susceptibility (Miller et al., 2009). With regard to gene–environment research, it is likely that different forms of psychological stress may be important for particular genetic vulnerabilities to specific diseases. Thus, for example, chronic forms of stress may be important for particular types of genetic predisposition and disease, whereas acute major life events

may be especially important for activating specific genetic predisposition to other kinds of conditions. Much as attention to proper definition and assessment of psychological stress has been a lesson learned from the recent gene–environment interaction literature, care in defining and assessing particular forms of psychological stress will be important in the coming years as more sophisticated genetic and biological multifactorial models are investigated.

Abstract

Strikes involve an apparent waste of resources that might otherwise have been divided between the employer and the workers. Although it has been argued that strikes might be caused by political conflicts within unions, or as a means to demonstrate the union's toughness with an eye to future negotiations, economic models of strikes generally view the apparent waste as a necessary cost of credibly transmitting private information regarding the actual size of the surplus available to be divided. For example, an employer who knows that sales prospects are poor may find it difficult to convince the union that this is the truth, as opposed to self-serving cheap talk. A strike then serves to verify the truth of the employer's claim, since if sales prospects are in fact good, the employer will be anxious to settle, even on terms favorable to the union. Empirically, strikes are rare, and in recent years strike activity has diminished considerably. The level of strike activity has been shown to be sensitive to fluctuations in the general level of economic activity, with fewer strikes occurring during recessionary periods. Collective bargaining legislation also has been shown to have some influence on the level of strike activity, and this is especially true of legislation constraining the use of replacement workers, depending on whether the replacements are temporary or permanent.

In perfectly competitive markets, wages are fully determined by supply and demand, and it is futile for workers to attempt to raise their wages by threatening to strike. But labor markets rarely conform to the competitive ideal, and it is generally the case that the value of labor to the employer is greater than the workers' opportunity cost, so that there is a surplus to be divided between the worker and the employer. A strike is a suspension of production while both the sides argue about how to divide this surplus.

Strikes are generally viewed by economists as a wasteful activity. After the strike is eventually settled, it is obvious that agreement could have been reached without any suspension of productive activity, on terms that would have been more favorable for both sides. Indeed, if one had a theory capable of predicting how long the strike would last, and what the settlement terms would be, the theory would be self-contradictory, in the sense that the employer and the union would both do better by reaching an agreement without a strike, rather than follow the predictions of the theory. This has been called the Hicks Paradox (Kennan, 1986), since it is implicit in Hicks's analysis of the relationships between anticipated strike durations and settlement terms guiding the employer's decisions of how much to concede to the union, and the union's decisions about how long to resist. Hicks gave an insightful discussion of the conditions under which some strikes will nevertheless occur:

> Weapons grow rusty if unused, and a Union which never strikes may lose the ability to organize a formidable strike, so that its threats become less effective. The most able Trade Union leadership will embark on strikes occasionally, not so much to secure greater gains on that occasion (which are not very likely to result) but in order to keep their weapon burnished for future use, and to keep employers thoroughly conscious of the Union's power.
>
> Under a system of collective bargaining, some strikes are more or less inevitable for this reason; but nevertheless the majority of actual strikes are doubtless the result of faulty negotiation …. Any means which enables either side to appreciate better the position of the other will make settlement easier; adequate knowledge will always make a settlement possible. The danger lies in ignorance by one side of the other's dispositions, and in hasty breaking off of negotiations.
>
> …
>
> Yet conciliation, however intelligently operated, cannot prevent strikes altogether. There will still be some strikes necessary to keep the Union "in training", and further and more important, there remains the possibility of a difference of opinion between the Union leaders and their rank and file. The leaders may be convinced that they have got the best that could be got by any method, but they may fail to convince their supporters.
>
> Hicks, 1932, The Macmillan Company

This points to three possible lines of thinking along which an economic theory of strikes might be developed. First, it might be rational for the union to endure a costly strike this time in order to establish a credible strike threat that can be used to extract concessions from the employer in future negotiations. Second, the union is a political entity rather than a single agent, and there may be differences of opinion among the union members regarding acceptable terms of settlement. Third, either side might have private information that cannot be credibly transmitted to the other side without going through a costly work stoppage; in effect, a claim by one side that the pie is actually smaller than the other side thinks can be proved only by demonstrating a willingness to forgo some known fraction of the pie.

The first of these lines has not really been pursued in the literature, while the second was developed by Ross (1950), and used by Ashenfelter and Johnson (1969) to provide an informal basis for an empirical analysis of strike activity. But the main developments in the more recent literature have been based on the idea that private information is the fundamental cause of strikes. Indeed, Hicks's remark that "adequate knowledge will always make a settlement possible" applies to all three of the theoretical approaches just mentioned.

The main idea underlying private information theories of strikes can be illustrated using a simple example. Suppose

a union negotiates a contract with an employer who has private information about the value of the workers' labor. From the union's point of view this value, V is a random variable with a distribution F that is assumed to be common knowledge; on the other hand the employer knows the realized value of this random variable, which always exceeds the union workers' opportunity cost, w_0. The employer's informational advantage may be offset by giving the union the power to make offers that the employer must accept or reject. If the union demands wage w, the probability of acceptance is $1 - F(w)$, so the union's optimal demand, w^* satisfies the condition

$$w^* = \arg\max_w w(1 - F(w)) + w_0 F(w)$$

Suppose that the support of F lies in the interval (a, b), with $w_0 \leq a$, so that there is a positive surplus to be shared between the employer and the union for any realization of the random variable V. It is easy to see that the union should make a demand such that some employer type is indifferent between acceptance and rejection. In the simplest case, V takes just the two values b and a, with probabilities p and $1 - p$. If the union demands the high value, the expected payoff is $pb + (1 - p)\, w_0$, while if the union demands the low value, it will be accepted for sure. Thus, it is optimal to make the more aggressive demand if

$$pb + (1 - p)w_0 \geq a$$

If this condition holds, there is a strike whenever the realized value of V is low. This strike condition can be rewritten as

$$p \geq \frac{a - w_0}{b - w_0}$$

Thus, the union's decision on whether to use the strike threat is influenced on the one hand by the likelihood p that the employer's valuation is high, and on the other hand by the difference between high and the low valuations (both measured relative to the workers' opportunity cost w_0). A large spread between a and b means that the firm's private information is relatively important, so that a strike threat is worthwhile even if the probability of acceptance is low. The right side of the above inequality gives a threshold for p below which the strike threat is not worthwhile. In this case there is a 'pooling' outcome, in the sense that the wage settlement is the same for both employer types. When p rises above the threshold it is optimal to threaten a strike, but further increases in p reduce the probability that a strike will actually occur. In this case there is a 'screening' outcome: the high employer type agrees to a high wage, while the low type rejects the union's demand. This simple model is analyzed in more detail in Kennan (1986).

When the firm's valuation has a continuous distribution, the union's optimal policy again might involve either pooling or screening. If there is an interior solution, it must satisfy the first-order condition

$$(w^* - w_0)h(w^*) = 1$$

where h is the hazard function, $h(w) = \frac{f(w)}{1-F(w)}$. For example, if the distribution of V is exponential, so that $1 - F(w) = \exp(\theta(a - w))$, then $h(w) = \theta$ for $w \geq a$. In this constant–hazard case there is only one possible interior solution, and the optimal demand is given by

$$w^* = \max\left\{w_0 + \frac{1}{\theta}, a\right\}$$

If θ is large, the distribution of V is concentrated near a, so there is not much to be gained by making an aggressive demand, and the pooling solution is optimal. Otherwise the union demands $w_0 + \frac{1}{\theta}$, and the probability of a strike is $1 - \exp(\theta(a - w_0) - 1)$.

Another natural example is the case where V has a uniform distribution on (a, b). Then the first-order condition is

$$\frac{w^* - w_0}{b - w^*} = 1$$

Thus, the optimal demand is given by

$$w^* = \max\left\{\frac{1}{2}w_0 + \frac{1}{2}b, a\right\}$$

In this case the probability that the employer accepts the union's demand is

$$q = \frac{1}{2}\frac{b - w_0}{b - a}$$

Bulow and Roberts (1989) show that the analysis of bilateral exchange with private information is closely related to standard models of monopoly pricing. Consider a monopolist facing a linear demand curve

$$p = b - (b - a)Q$$

with constant marginal cost c, and a capacity constraint $Q \leq 1$. The monopolist equates marginal revenue and marginal cost, unless marginal revenue is still above marginal cost at the capacity constraint, in which case the optimal output is $Q = 1$.

Equating marginal revenue and marginal cost means choosing Q so that $c = b - 2(b - a)Q$, with $p = \frac{1}{2}c + \frac{1}{2}b$, while the price at the capacity constraint is $p = a$. Thus the optimal price is

$$p^* = \max\left\{\frac{1}{2}c + \frac{1}{2}b, a\right\}$$

which matches the solution of the union's problem, with $c = w_0$. Indeed, the union acts as a monopoly seller of labor, facing a tradeoff between a low wage and a high quantity, or the reverse, where the quantity is the probability that the employer will accept the union's wage demand.

A much more extensive analysis of bargaining models with private information, allowing for private information on both sides, is presented in Kennan and Wilson (1993), with applications to legal conflicts as well as labor negotiations. A general treatment of games with private information, with many bargaining examples, can be found in Myerson (1991). Kennan and Wilson (1993) discuss three varieties of private information models. The simple examples above are screening models, which become more interesting when the union makes a sequence of offers (with a delay period between offers), rather than a single 'first and final' demand. When the informed party can make offers (or counteroffers) additional complications arise, because the offer that is made conveys a signal of the private information underlying the offer. In contrast to these screening and signaling models, attrition models treat the surplus to be divided as an indivisible object, with each side trying to convince the other that it can tolerate a longer strike; eventually the weaker side concedes and the other side takes the

whole surplus (although a large fraction of the surplus is generally lost in a protracted conflict).

In a series of papers, beginning with Cramton (1992) and Cramton and Tracy (1992), and summarized in Cramton and Tracy (2003), Cramton and Tracy developed a private information model of strikes and 'holdouts,' which occur when the old contract expires without agreement on a new one, but work continues without a strike until a new agreement is reached (and the new contract is backdated to the expiration of the old contract). Cramton and Tracy (1992) show that holdouts are empirically important, and that they can be interpreted as the outcome of a signaling game which is like a strike except that the stakes are smaller. The crucial assumption is that, although the opportunity cost of a strike is privately known to the firm, it is common knowledge that the opportunity cost of a holdout is proportional to the opportunity cost of a strike. In effect, the parties have a way of using a small-scale conflict to reveal information which could otherwise lead to a strike.

The 'joint cost' model of strikes, due to Reder and Neumann (1980) and Kennan (1980), simply postulates that whatever the negotiation process might be, it is reasonable to suppose that there will be less strike activity with strikes being more costly, where the relevant measure of cost is the joint loss suffered by both sides taken together. This simple model has been used quite extensively to guide empirical work, although in practice it is often difficult to isolate differences in joint costs in a sample of contract negotiations, and in particular it is difficult to isolate variables that affect the cost of a strike without affecting the size of the surplus.

Empirical Analysis of Strike Activity

Strikes are rare. In 2013, there were only 15 strikes in the United States involving 1000 workers or more. The total number of workers involved in these strikes was about 54 500, and the number of work-days lost was about 289 900. Most of these strikes involved local government workers. There were only 6 strikes in the private sector, with a total of 13 200 workers involved, and a loss of 39 500 work days. There are about 11 million workers employed in establishments with 1000 workers or more, so the chance of being involved in a strike (in the US private sector in 2013) was about one in a 1000.

Figure 1 shows the number of work-days lost due to large strikes in the United States and Canada over the period 1946–2013 (a large strike in Canada means a strike involving 500 workers, so the levels of the two series are not comparable). Strike activity has declined quite dramatically, especially in the United States, although one large strike can cause a big jump in the data (as in the case of the 6-month strike by 135 000 actors involved in making TV commercials in the United States in 2000). Although it is difficult to obtain comparable data for many countries, the decline in strike activity over the last 40 years or so seems to have been quite widespread.

Fluctuations in Strike Activity

There is an extensive empirical literature analyzing the relationship between strike activity and business cycle fluctuations. The main conclusion from early work in this area is that strikes are more frequent when general economic conditions are good. Although this conclusion is supported by a considerable body of evidence, it is of limited interest because it lumps together strikes of all sorts, including many minor disputes that occur during the term of ongoing labor contracts. More recent work has attempted to determine whether economic conditions affect the incidence of contract strikes. This work largely relies on North American data, because unions in the United States and Canada generally negotiate contracts covering clearly defined periods of a few years, so that one can count the

Figure 1 Strike activity.

number of negotiations that might lead to a strike, and use this to measure strike incidence.

The empirical results on strike incidence are well summarized by Card (1990); some more recent findings are reviewed by Cramton and Tracy (2003). Surprisingly, the evidence indicates that strike incidence and duration move in opposite directions over the business cycle. Strike incidence is generally found to be procyclical, although the relationship between strikes and general economic conditions is not strong enough to dominate other sources of variation, so that a long time series is needed to establish the result. Although less work has been done on cyclical movements in strike duration, there is solid evidence that duration moves counter-cyclically. Some attempts have also been made to distinguish between the effects of cyclical fluctuations in product markets and in labor markets. There is no clear pattern in these results, and there is no clear theoretical reason for making the distinction in the first place.

There is also an old empirical literature, starting with Yoder (1938), showing pronounced seasonal patterns in strike activity. The evidence on seasonality is discussed by Kennan (1986), who pointed out that although the seasonal fluctuations are large there has been no serious attempt to explain them, a comment which apparently still applies in 2014.

Effects of Collective Bargaining Legislation

Strike activity is clearly affected to a large extent by laws governing the tactics available to workers and employers as they negotiate over the division of the employment surplus. This is a large subject in itself, which is not dealt with here; Cramton and Tracy (2003) give an overview of some of the main issues with respect to North American legislation, and Campolieti et al. (2014) analyze the empirical relationships between variations in collective bargaining laws and strike incidence and duration across Canadian provinces.

One topic worth considering briefly is the use of replacement workers. As Schnell and Gramm (1994) point out, it is important to distinguish between temporary replacements, used to maintain production during the course of a strike, and replacement workers who permanently displace the striking workers from their jobs. Gunderson and Melino (1990) show that prohibiting replacement workers (in Quebec) increases strike duration, and also increases strike incidence (Table 3). They also argue that replacement workers reduce the joint cost of a strike, so prohibiting replacements should reduce strike incidence according to the joint cost theory. But since the Quebec prohibition (which came into effect in 1977) covered both temporary and permanent replacements, there is no way to disentangle the separate effects of these variables. A reasonable interpretation is that temporary replacements reduce the cost of a strike, while permanent replacements reduce the size of the surplus to be divided between the employer and the union.

The analysis of the effects of replacement workers in Kennan and Wilson (1989) is concerned with strike duration, rather than incidence. The availability of replacement workers truncates the distribution of employer valuations from above, so if replacement workers are banned, longer strike durations are needed to reveal the firm's valuation (because strikes continue beyond the point where it has been established that the valuation is above the truncation point).

The same logic implies that prohibiting replacement workers increases the incidence of strikes. In the case of the exponential distribution discussed above, if there is an interior solution without replacement workers, then the wage demand is

$$w^* = w_0 + \frac{1}{\theta}$$

and the strike incidence is

$$1 - \exp\left[-\theta(w^* - a)\right]$$

If the truncation point $\widehat{w}$ is greater than w^*, there is no effect on strike incidence: the union makes the same demand regardless of whether replacements are allowed, and there is a strike if $V < w^*$.

If $\widehat{w}$ is less than w^*, then the optimal demand when replacement workers are permitted is $\widehat{w}$, and there is a strike only if the firm's valuation is below this point. But this means that the replacement workers are irrelevant – the employer would not hire them in any case (although the union does not know this). When replacements are not allowed, there are also strikes when $V \in (\widehat{w}, w^*)$. Thus allowing replacement workers increases the incidence of strikes.

Abstract

The Strong Program in the sociology of knowledge is a set of methodological requirements about the proper way in which social scientists and historians should analyze and explain knowledge, including scientific knowledge. Such investigations should be causal, impartial, symmetrical, and reflexive. The article explains and illustrates these requirements. The basis of the argument in their favor is that these requirements are expressive of a truly scientific orientation in which knowledge is treated as a natural phenomenon. The article ends with a brief introduction to some case studies from the history of science that show the Strong Program in action.

The 'Strong Program' is a set of methodological requirements about the proper way to conduct sociological enquiry into the nature of knowledge, including scientific knowledge. The program enjoins the investigator to adopt four requirements: (1) causality, (2) impartiality, (3) symmetry, and (4) reflexivity. The requirement of 'causality' means that the aim of the sociologist is not merely descriptive but also explanatory. What brings about and sustains a body of knowledge? 'Impartiality' means that, for the purposes of the investigation, the investigator disregards his or her sense of whether the beliefs under scrutiny are true or false, or rational or irrational. Equal curiosity should be expended on both sides of the evaluative divide. This does not mean that an investigator should have no opinions. The requirement is that these opinions should not, for example, lead them to study one side of a scientific dispute while leaving the other side unexamined because it seems right or obvious. 'Symmetry' means that this equally distributed curiosity should issue in the same general kinds of sociological explanation regardless of how the knowledge is evaluated. All beliefs confront the same problems of credibility and depend on the same contingencies. True beliefs have no more intrinsic credibility than false ones. Finally, 'reflexivity' means that sociologists of knowledge must not claim access to any transcendent standpoint. Put simply, no sociological theory of knowledge is acceptable unless it applies to itself. These requirements all stem from the desire that the approach of the sociologist of knowledge should be scientific in character. It should embody the same naturalistic spirit that now routinely informs work in such fields as physics, engineering, and biology. Despite its scientific motivation, the Strong Program is widely perceived by critics as being antiscientific. To offset such misunderstandings, each of the four requirements calls for amplification and defense.

Causality

The sociological causes at work in the creation of a body of knowledge shared by the members of a group range from the traditions, customs, conventions, and institutions of the group to the current problems and specific interests of its members. A sociologist of science will attend to the role of different disciplinary and professional traditions, the presence of dominant or competing research schools, and the interactions between scientists and other significant institutions such as the government, the church, and the military as well as the institutions by which knowledge is transmitted, such as universities and professional bodies.

The commitment to causality does not mean that sociologists believe that only sociological causes are at work. It is self-evident that all belief systems, whether scientific or nonscientific, are the achievements of biological entities (namely, human animals) that interact with one another as social animals and who also (and simultaneously) interact collectively with their material environment. People have their eyes open, and their sensory inputs influence belief just as do their susceptibilities to one another as social animals. Unless human agents had effective sense organs, as well as a range of innate propensities, they could neither create nor transmit a shared culture. Knowledge cannot be 'purely' social and no responsible sociological analysis has ever carried such an implication.

It follows that sociologists can only contribute part of a complete explanation of cognition. Sociologists must always work alongside other specialists, such as psychologists. Conversely, no adequate account of human knowledge can ever proceed without due acknowledgment of the role of the social. The 'strength' of the program lies in the necessity, not the sufficiency, of the social dimension.

The False Charge of Idealism

The idea that material reality plays no role in human knowledge is called 'idealism,' that is, the metaphysical doctrine that there is no material world that can constitute an independent object of knowledge. Idealists fuse the subject and object of knowledge together and treat both as spiritual, or mental, in nature. The accusations of idealism that have been directed at the Strong Program are incorrect. They have arisen through the misrepresentations of the critics. For example, Bruno Latour (1993) says the Strong Program is one of a family of theories based on the idea that knowledge has two ingredients, 'nature' and 'society,' which trade off against one another in a zero-sum game – the more of the one ingredient meaning the less of the other. Viewing the Strong Program from within this framework, Latour

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85033-3

presents it as an extreme stance where one of the ingredients, nature, actually makes zero contribution. The 'strength' of the program is thus wrongly said to reside in the claim that knowledge (and indeed reality) is purely social.

This false reading is widespread. Thus, some critics implicitly accept a zero-sum picture but insist that nature plays some role rather than no role. It is assumed to be an empirical question to decide just how much influence is exerted by nature in comparison to that exerted by society. A variant of this argument underlies the claim that the Strong Program is incompatible with acknowledging that the natural sciences have a good record of predictive success. The accusation rests on the premise that if scientists were only attending to what is going on in society, and were not attending to what is happening in nature, their ability to make predictions would be unintelligible. The inference is correct, but the premise is false. The assumption behind the Strong Program is that scientists understand nature collectively, through society, not in spite of it. An analogy may be of help in seeing where the critics have gone wrong. Society no more interferes with knowledge than the eye interferes with vision. The eye, like society, operates as the relevant organ of cognition and as a necessary constituent of it. No one asks 'how much' of our visual experience is contributed by the eye, and 'how much' by the object seen. We might ask 'what' is contributed, but not 'how much.' The latter question makes no sense, and neither does the allegedly 'empirical' question of 'how much' of knowledge depends on nature and 'how much' on society.

The Role of the Social

How do social processes enable scientists to have access to the world? The answer given many years ago by Thomas Kuhn (1962) illustrates the kind of answer available to the sociologist. Kuhn argued that cognition within a group of scientists is coordinated by reference to a shared exemplar or paradigm, that is, a concrete achievement, recognized by the group and used as a resource on which to model their creative activity. By virtue of their shared orientation toward that achievement, and their knowledge of its standing in the eyes of others, members of a group endow it with a normative status. The paradigm indicates the proper way to proceed. It will be evident that something is constituted as a paradigm by being accepted as a paradigm – in the way that money is constituted as money by being regarded as money. In these self-referential and self-reinforcing ways, society gets woven into the fabric of knowledge and into the struggle to make sense of intransigent, real-world processes.

Impartiality and Symmetry

The reference to Kuhn also points to the correct way to understand impartiality and symmetry. Kuhn did not say that the idea of a paradigm merely helps the historian to make sense of old-fashioned theories. He applied the idea to all cases of shared knowledge whether past or present, or whether accepted or rejected by the historian. He was searching for invariant, social principles of scientific cognition. Thus, it is always true that a shared interpretation of the world has to be sustained by some mechanism of social coordination and that mechanism must work in the face of continuing difficulty, anomaly, and threat of fragmentation. Every shared approach to nature must overcome the problem that our experience can be given more than one interpretation. Every cultural institution requires that the behavior of its participants be aligned rather than allowed to lapse into individualistic anarchy. To understand the ways in which these ubiquitous problems are confronted and solved calls for a perspective that picks out the general mechanisms by which social and cultural order are maintained. This is the point of the methodological demand for impartiality and symmetry.

Reflexivity

In the eyes of its critics, the requirement that the Strong Program must be applicable to itself immediately raises the specter of self-refutation. If the claims of the sociologist themselves transcend sociological determination, then the sociologist is admitting that the sociology of knowledge is false. If the claims of the sociologist are not exceptions, but are also socially determined, then why should anyone believe what the sociologist says? The claims will be mere ideology or the product of social bias. The basis of this objection goes back to the theme of causation. Reflexivity looks self-refuting, but only if it is tacitly assumed that the sociologist's vision of knowledge sees knowledge as wholly the product of custom, tradition, prejudice, or ideology, that is, treats it as a collective fantasy. Once it is accepted that society is a necessary ingredient of all knowledge, including science, then the role of society can be studied in a matter of fact manner. It can no longer be assumed that sociological causation operates as a fatal contaminant.

Ideological Limitations on Causality

In adopting the requirements of causality, impartiality, symmetry, and reflexivity, the sociologist or historian of science faces a major obstacle. These requirements seem to run counter to deep-rooted aspects of common sense. In general, human curiosity has a markedly partial and asymmetric structure. Social actors typically confine the request for causal explanation to the breakdowns in their routine expectations or evaluations. When things go smoothly, they do not ask why, because they typically feel that nothing more needs to be said. This common-sense asymmetry makes sense in the context of daily life, but sociologists are seeking general results and are working within a broader context. Their professional curiosity is symmetrical, not asymmetrical like common sense.

For these reasons, the Strong Program is in direct opposition to the conclusions of philosophers such as Imre Lakatos (1971) who have sought to recast common-sense asymmetry into a set of general methodological guidelines for the writing of the history and sociology of science. These writers require the analyst to identify what is deemed to be 'rational' in a body of scientific work and treat this as a baseline. They encourage the historian and social scientist to think that the normal workings of causality do not apply to what is rational, or that qualitatively different kinds of causes are in operation when things

proceed rationally compared with when there is a deviation from rationality. Although this is not their terminology, they explain rational behavior teleologically, by appeal to 'final causes,' and deviations from rationality in terms of 'efficient causes.' Remarkably, some philosophers have even taken this argument to the extreme of claiming that while illusory perception calls for causal explanation, veridical perception does not. No psychologist or physiologist would approach perception in this way – just as no medical scientist would say there are causes for disease but no causes for health, and no engineer would say there are causes for why bridges collapse but none for why they stay up. But if these specialists can overcome the assumptions and asymmetries of everyday life and give their professional curiosity a locally symmetrical character, then so can the sociologists.

The universality of the causal perspective, and the need to avoid placing arbitrary restrictions on the scope of causality, should be self-evident from a scientific standpoint. How can philosophers oppose this when, at the same time, they see themselves as defending science against its detractors? Anthropologists have long known the answer to this question. The selective use of causality is a technique widely used to make the basic norms and beliefs of a culture appear distinct from nature and hence take on a form that renders them deserving of special respect.

Durkheim (1915) drew attention to the important distinction between the sacred and the profane and traced the way in which groups protected their norms and institutions by treating them as sacred. To be sacred was to be untouchable, and that means untouchable by the mundane categories of cause and effect. It appears that these techniques are not confined to members of the traditional societies whose culture interested Durkheim. Such strategies are alive and well in the writings of philosophers of science. Nevertheless, the strategy of 'defending' science by treating it as sacred is a strange one. Today's science has no place in it for the sacred so, in thus defending it, the philosophers are betraying it.

Crucial Experiments

One of the most profound insights into the working of science was furnished by the physicist Pierre Duhem in his classic *Aim and Structure of Physical Theory* (1914). Duhem argued that there is no such thing as a crucial experiment and, in developing this claim, he uncovered important general truths about the nature of meaning and reference.

Consider two rival theories T1 and T2, both of which are capable of explaining a body of experimental results. How can scientists decide which is correct? The standard view was that it was possible to perform a 'crucial' experiment. An experiment must be found in which T1 and T2 both make predictions regarding the outcome but where the predictions diverge, so T1 predicts E while T2 predicts not-E. Such an experiment might permit the elimination of one of the theories and the (cautious) retention of the other.

Duhem argued that this analysis does not do justice to the real predicament, or the real resources, of the experimenter. In reality, argued Duhem, no theory can be tested in isolation from a mass of background assumptions (A). Some of these assumptions can be made explicit, but many will be tacit or unknown. Once the role of the background is brought into the picture, then it is clear that what is under test is not T1 or T2, but a logical conjunction of theory and background assumption, that is, (A&T1) or (A&T2). A false prediction, say by T1, thus carries the implication, not that T1 is false, but that either T1 is false or A is false. This makes every refutation equivocal. It means that T1 might be reconciled with the experimental outcome by altering the background assumption A, for example, by blaming the outcome on impurities in the chemicals, or faults in the wiring, or inadequate experimental shielding, or hitherto unappreciated friction effects, etc.

It might look as if Duhem is merely showing how the discipline of experiment can be evaded, but the point goes much deeper. Duhem had put his finger on the basic cognitive mechanics by which a Kuhnian paradigm is elaborated in the face of an endless string of anomalies. Every anomaly could be counted as a refutation, but it is not. It is seen as a puzzle and past achievements are seen as resources for solving the puzzle. Duhem was not describing bad science, but normal science. Duhem had his own answer to how, and to what extent, this room for maneuver should be exploited. He said that, when adjusting the background assumptions, a scientist must use 'good sense.' As far as it goes this is correct. Not any attempt to rescue a theory from refutation will carry credibility. It may demand contradicting other results, and this may be felt to impose too great a cost. The rescue may not be worth it. A sociologist of science will see at once that the argument has now moved decisively into the realm of the social. When a group makes a decision about such costs, they are making decisions about the conventions and institutions they want to sustain. The voice of 'good sense' is the voice of the group.

Meaning Finitism

Duhem's argument can be generalized. It applies to every single act of concept application, whether inside or outside of science, and takes the sociologist to the heart of the phenomena of meaning, concept learning, and concept use. The 'negotiability' of scientific prediction translates into the 'negotiability' of all meaning. Unfortunately, the generality of Duhem's insight has escaped the philosophical critics of the sociology of knowledge. To see what is at stake, consider how simple words are learned and applied.

All learning must go back to a process known as 'ostensive definition.' The word 'cat' is learned by competent users pointing out a number of examples in the hope that the learner will grasp the meaning. The learner must then move from the finite number of examples in the learning set to a new application to a putative cat that has not been encountered before. The attempts will be monitored and, if necessary, corrected by the teachers. Sometimes concepts are learned by verbal definitions, but the words in the definition must be familiar and, ultimately, these will have been defined ostensively.

It is a mistake to think that ostensive definition can 'fix' meanings. It cannot, but this is not because ostensive definition is defective but because the notion of 'fixed' meanings is wrong. A concept can no more be associated with a fixed meaning than a theory can be associated with a fixed prediction. Past

instances of a concept do not determine future applications because a whole network of background assumptions and contingencies is always in play. This important principle is called 'meaning finitism.'

Meaning finitism rules out a familiar line of criticism directed at the sociology of knowledge. This criticism depends on the myth of fixed meanings and is exemplified in the work of the philosopher John Searle (1995). Searle acknowledges that a word such as 'cat' is learned on the basis of a finite number of examples, but he assumes that the language learner has the capacity to extract 'fixed' meanings from the examples. Thus,

> What counts as a correct application of the term 'cat' … is up to us to decide and is to that extent arbitrary. But once we have fixed the meaning of such terms in our vocabulary by arbitrary definitions, it is no longer a matter of any kind of relativism or arbitrariness whether representation-independent features of the world satisfy those definitions …. (Searle, 1995: p. 166)

Expanding on this theme, Searle says that how one uses the word 'cat' is up to him or her, but whether there is an object that "satisfies that use, is a plain matter of (absolute, intrinsic, mind-independent) fact" (p. 166).

But an object 'satisfies' a concept in the same way that an experimental result 'satisfies' the prediction from a theory. Had Searle taken note of Duhem's expert testimony, he would have known that 'satisfaction' is always a negotiable relationship, not something that can ever be treated as 'fixed.' Rather than shutting down sociological curiosity, as Searle thinks, the conventions of concept application are as sociologically problematic as Duhem's 'good sense.'

Relativism

One of the most frequent objections to the Strong Program is that it is 'relativist.' The supporters of the Strong Program are happy to embrace the label provided the definition of the word 'relativism' is clear and appropriate. To meet these requirements, the central idea of relativism must be disentangled from other ideas with which it is often confused. Thus, it can be accepted that sociologists of knowledge are relativists insofar as they see knowledge as a natural phenomenon, located in space and time and subject to causal laws. Knowledge will then have a contingent character that precludes it ever achieving a status that could justifiably be described as 'absolute.' Absolute cognition is a phantom and would place knowledge outside the realm of nature. Thus, if 'relativism' is simply the denial of 'absolutism,' and the rejection of absolutism is a necessary and sufficient condition for relativism, then the Strong Program is relativist, and rightly so.

Unfortunately, many self-proclaimed antirelativists reject this simple definition of relativism. They claim that they are not absolutists, but insist that this does not commit them to relativism. They claim to be neither relativists nor absolutists. Thus, the rejection of absolutism is taken as a necessary, but not a sufficient, condition for relativism. The assumption is that the definition of relativism must involve a further necessary condition. Typically, and as already indicated, this extra condition involves imputing to the relativist some form of philosophical idealism or some form of irrationalism e.g., the belief that 'anything goes'). Critics thus use an eclectic definition, but in so doing they conflate questions that should be kept separate. They run together different intellectual traditions and fail to draw obvious distinctions. The dichotomy between absolutism and relativism is not the same as the dichotomy between idealism and materialism or between rationalism and irrationalism.

Converging Evidence

It was a slogan of the Enlightenment that a rational man proportions his belief to the evidence. What do sociologists have to say about the role of evidence in science? Critics maintain that sociological causes may explain beliefs that are not warranted by evidence, but insist that the attempt to explain warranted beliefs is misguided. Knowledge of the evidence itself is sufficient to explain warranted belief.

Consider the accumulation of evidence over time and its capacity to modify belief. Suppose two rival theories T1 and T2 are adopted, respectively, by subgroups G1 and G2. Members of G1 give a high a priori probability to T1 and a low a priori probability to T2, while members of G2 do the opposite. Let it be granted to the sociologist that these a priori probabilities can be explained by observing that the theories help further the interests of the respective groups.

Now, suppose that unbiased experiments are carried out to test the consequences of the two theories. Evidence accumulates that yields a new a posteriori probability for the two theories, making, say, T1 more probable and T2 less probable in the eyes of both G1 and G2.

Will it still be true that the beliefs of the members of G1 and G2 are socially explicable or should it be said that the burden of explanation has, in some way, begun to shift from the social to the rational? There are some mathematical results, called convergence theorems, which seem to accomplish this transformation. They show how, as evidence accumulates, the a posteriori probability will eventually converge on 0 (false) or 1 (true). Evidence eventually 'washes out' the initial, socially caused, distribution of belief and, it seems, leads to new beliefs based solely on rational rather than social considerations.

Such an interpretation, however, cannot be right. Convergence theorems only work under highly restricted conditions. They require the randomized and logically independent nature of the incoming information. The theorems also apply to a limiting case, that is, to the convergence of an infinite sequence of events. These conditions are not met in reality. All empirical sequences are finite, and experiments are not performed randomly or independently. The beliefs that are the end product of experimentation are therefore no less the proper objects of sociological enquiry than the a priori probabilities at the beginning.

Inductive Strategies

The lesson to be learned is that evidence-based belief should not be set in opposition to belief caused by social processes. To drive

this point home, it will be appropriate to examine another celebrated argument, namely, Rudolf Carnap's (1952) theory of inductive confirmation. Carnap saw evidential support as a logical relation that, under suitable circumstances, was capable of rigorous definition and mathematical formulation. Here, if anywhere, would be a demonstration of the irrelevance of the social to the rational conduct of science. In fact, Carnap's analysis generated the opposite result. It turned into a demonstration of the ineradicably social character of inductive confirmation.

Carnap began by confining his analysis to a simplified model of a world with a specified number of objects and properties and a formally defined 'language' for the description of possible states of affairs. The aim was to make it possible to specify the precise logical content of any proposition, whether a hypothesis h, or a piece of evidence e. It would then be possible to measure inductive support by defining it in terms of an overlap (or partial entailment) between the states of affairs specified by the propositions in the language. These restrictions are hardly designed to be friendly to the sociological perspective, but this is what makes the exercise an interesting one. It makes it a severe test of the sociological approach.

Carnap found that there was no unique confirmation function, that is, no unique formula $c(h,e)$ that would accord a numerical value to the degree of evidential support of e for h. It transpired that there were an infinite number of possible functions that could perform this role. To accommodate this fact, Carnap introduced a parameter λ (lambda) into the confirmation function. This parameter could assume any value between zero and infinity. Each value of λ, said Carnap, represented a possible inductive strategy, that is, a greater or lesser willingness to make risky generalizations. Thus, all inductive inferences depended on an inductive strategy, and inductive strategies must be supplied by the subject who is seeking to learn about the world.

Carnap expressed the point psychologically and presented the choice of inductive strategy as a matter of individual preference. If confirmation theory is intended as a model of science, however, this individualistic formulation needs to be amended. Inductive strategies are matters of consensus not subjective preference. They are embodied in the conventions and institutions of groups of scientists. In short, λ is a social parameter and inductive inference is a socially structured form of cognition. Sociological enquiry is needed to identify the causal conditions determining the inductive strategy of any given group.

Can There Be a Sociological Analysis of Mathematics?

Can there be a Strong Program analysis of mathematics – that is, not just a sociology of mathematicians, their recruitment, organizations, status hierarchies, quarrels, and professional lapses, but one that deals with the knowledge itself? One way to appreciate the scope of this question, and the possibilities for answering it, is to imagine mathematics organized into a deductive system. In such a system, mathematical results take the form of theorems, which follow rigorously, according to clearly stated rules of reasoning, from clearly stated axioms. In reality, mathematics is much more disjointed and ad hoc but the idealized case is a useful starting point because (once again) it makes the minimum of concessions to the sociologist.

In an axiom system, there are two points of entry for sociological enquiry. First, where do the axioms come from? How are they chosen and what gives them meaning, credibility, and interest? Second, where do the rules of inference come from? What gives these rules their power to compel assent? It is always possible to give a metaphysical answer to such questions and thereby create the impression that there is no need to exercise empirical curiosity on such matters. It might be said that the axioms are 'self-evident' or that one possesses 'intuition' into the validity of basic deductive arguments. This will not satisfy those with a scientific commitment to causal enquiry. To meet this requirement, the answers will have to take a different form, namely, an appeal to psychosocial causation, that is, the form codified in the Strong Program.

The status of the basic concepts and modes of inference used in mathematics has long been a matter of professional interest for mathematicians themselves. There has been an important strand in the history of mathematics that has attempted to illuminate such problems. The fate of this foundational enterprise therefore needs to be understood before assessing the prospects for a sociological analysis of mathematics.

The development of the differential and integral calculus in the eighteenth century greatly increased the power of mathematics but its procedures lacked rigor. To put the calculus on a firm foundation, its fundamental concepts were eventually defined in terms of more basic arithmetical operations. These successes led to further questions. If the calculus is justified by arithmetic, what is the justification for arithmetic? Guiseppe Peano cast arithmetic into an axiom system and, at the turn of the twentieth century, Gottlob Frege and Bertrand Russell set out to justify these axioms in terms of yet more basic logical concepts. Despite enormous effort, they failed to achieve their aims. Mathematicians use techniques that could not be defined in terms of the concepts of logic. Worse was to follow. Logic itself turns out to be susceptible to a variety of different formulations that are inconsistent with one another. And then there is the inevitable question of the justification of the deductive steps within these systems. Can deduction be justified? The answer is no – no more than induction can be justified (see Haack, 1976).

The collapse of the Frege-Russell program, and a number of similar foundational attempts, provided the motivation for Wittgenstein's *Remarks on the Foundations of Mathematics* (1956). Wittgenstein adopted a radically new approach. He acknowledged the failure of the justificatory project and represented mathematics in a radically different manner – as a sociological phenomenon. This is the meaning of his famous, but frequently misunderstood, analysis of rule following. Wittgenstein used the example of following a simple rule for generating a sequence of numbers such as 2, 4, 6, 8, etc. What is the character of the logical compulsion to say 8 after 6, and so on? In what does the necessity of the rule consist? All the candidate explanations that have been traditionally invoked turn out to be question begging. They take the form of rules for following rules and thus fail to engage with the problem at a fundamental level. By a process of elimination, Wittgenstein

excluded all explanations apart from the causal influence exerted on one another by the members of the community of rule followers as they seek to coordinate themselves and pursue their collective interests. Wittgenstein said that reasons come to an end, but he did not mean that two things are at work, reason taking the rule follower so far, and then social processes take over. His account was not dualistic. His blunt conclusion was that following a rule is to be understood as a custom, convention, or institution. If Wittgenstein's argument is right, then the sociology of mathematics is not merely possible – it is a necessary stance if the true nature of mathematical activity is to be brought to light.

Conclusion

The Strong Program was explicitly formulated by an interdisciplinary group in Edinburgh in the early 1970s. (For the development of this approach, see Barnes et al., 1996.) The aim was to codify the assumptions behind an emerging body of case studies of scientific practice – the better to defend them against outside criticism of the kind offered by philosophers. The lifeblood of the sociology of scientific knowledge, however, lies with empirical work. To name but a small sample of work that can be read as supporting the Strong Program, see Mackenzie (1981) on the history of statistics and its connections with eugenics, Shapin and Schaffer (1985) on the disputes surrounding Boyle's experiments with the air pump, Harwood (1993) on styles of research in German genetics before 1933, Kusch (1999) on the different theories of mind generated in different psychological laboratories in the early years of the twentieth century, and Bloor (2011) on the disputes in aerodynamics in the early decades of aviation. The Strong Program continues to serve its function because the importance of the rich body of empirical work on the nature of science is still obscured by misguided criticisms directed at its methodological foundations.

Structural Adjustment in Africa: Implications for Social Work

Lengwe-Katembula J Mwansa, University of Botswana, Gaborone, Botswana

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Africa, rich in diversity and natural resources, continues to reel from abject poverty and underdevelopment, especially in sub-Saharan countries. Its genesis in economic crises of the 1980s is disputed. This article contends that recognizing the complexities of these crises is essential to understanding Africa's current predicament and ways forward. I argue that the model of structural adjustment that the International Monetary Fund and World Bank imposed destabilized economic development and led to this policy's abandonment. In promoting social development, social workers can utilize models of empowerment through community practice to facilitate social and economic innovation in sub-Saharan Africa.

Introduction

The African continent, the second largest in the world at 30.2 million square kilometers (www.google.co.za) is home to more than 1 billion people, and the second most populated continent (UNDESA, 2006). According to UNESCO, Africa has 2000 languages and dialects, and almost as many clans (Mokhtar, 1990), mineral wealth, natural beauty, and a rich history. However, for many Westerners, Africa conjures up images of the Dark Continent and underdevelopment (Bates, 2012). Some, including scholars of international repute, forget that Africa is not a country but a continent of rich diversity, with 55 countries having their own sovereignty, distinct traditions and beliefs despite multifarious cultural nuance, bound together in a kaleidoscope of confounding perplexity.

Many Westerners do not realize how Africa has been locked into poverty, seeing its people as mendicants. Their reasons for the stagnation of the continent are similar to those expressed by advocates of Western economic models like Vishnu Padayachee (2010: p. 47) and 'ignored Africa's diversity in their rush to peddle simple nostrums of dubious merit'. Other than the economy, liberal economists have not viewed diversity and conflict as fundamental factors in the matrix for African development, utilizing instead Keynesian neoliberal economic models that do not incorporate original thinking or fit African realities. This includes African economists who claim allegiance to neoliberal economic ideological models espoused by the International Monetary Fund (IMF) and World Bank and the efficacy and necessity they recommend.

The Structural Adjustment Programmes (SAPs) were hailed as the best strategy for the economies of Africa, particularly Ghana, Uganda, and Zimbabwe, which had been celebrated as shining models of development (Devarajan et al., 2001: p. 54; Onimode, 1989a). However, the SAPs did not spare their economies because the ensuing economic crisis wreaked havoc and untold misery on their populations, particularly women, older people, rural people, and children. Life expectancy plummeted to the lowest levels from 49.0 to 45.1 and 61.7 to 47.4 for Uganda and Zimbabwe, respectively from 1987 to 1998 (CIA, 2012a,b), while maternal and infant mortality rates worsened. The majority of people in Ghana and Uganda continue to experience abject poverty with over 50% of Uganda's population living on $1 a day (United Nations Development Programme, 2012; *Millennium Development Goals Report*, 2012b).

Despite receiving substantial amounts of foreign aid, sub-Saharan Africa still suffers from wretched poverty, massive illiteracy, disease, squalor, and a poor general standard of living. This article recognizes the relevance of economic problems that bedevil the continent, but contends that remaining open-minded and recognizing the complex structural problems that have equally adversely affected human development in Africa is essential in avoiding flawed solutions to its problems. Not attributing the continent's woes to one factor is also significant in this.

Origins of the Economic Crisis

The 1980s and beyond are regarded as 'lost decades' for development in many sub-Saharan African countries. Some observers (Onimode, 1989b) located the genesis of deteriorating conditions of life at the time led many observers wrongly to locate the genesis of the economic crisis in sub-Saharan Africa to the Organisation of Petroleum Exporting Countries oil shock of the 1970s. Others locate the origin of the economic crisis in the period shortly after political independence (Hope, 1997). Hope blames the failure of a "policy framework, which put considerable faith in the role of government to plan and allocate resources for economic development" (p. 11). Easily forgotten or not sufficiently appreciated by many observers of Structural Adjustment Policies are the antecedents of development that fundamentally affected the internal logic of the structure of African economies given their diverse nature. The determining antecedents cited are: corruption, the Cold War, negative sequel of colonialism, slave trade, 'the rape of Africa' through blatant exploitation of natural resources, unequal terms of trade, and unending conflict, often instigated by Westerners pursuing their own interests (Rodney, 1972: p. 106; Kim, 2010).

The Cold War was a period of intense posturing with a great deal of uneasiness among countries such as Britain, the USA, and Russia. The aid-recipient nations had to demonstrate compliant behavior especially voting at global level, which had to be seen to support the fight against communism (Foot et al., 2003). Thus, creditor nations

through their lending institutions controlled the behavior of African nations – a carrot and stick approach. This patronage, had little or no benefits for the recipients and, in the process, the opportunity for development was lost.

Many observers (Heldring and Robison, 2012) question the role of colonialism in disrupting the fabric of Africa and creating conditions that foster enmity between ethnic groups leading to ongoing confliction in the continent. Peace in Africa has largely been undermined by conflicts, which seem endemic in many countries including the Democratic Republic of the Congo (DRC), Somalia, Uganda, Sudan, Nigeria, and Central African Republic (Gettleman, 2010). However, like other ancient civilizations, tribes indigenous to Africa experienced conflict among themselves and intertribal periods of war and peace. Historically, they used war to gain wealth and notoriety and established peace treaties with neighbors that would benefit them.

European colonizers, attempting to maintain control of their subjects, used intertribal conflict to divide and rule. Consequently, previously established interethnic relations were jeopardized and effectively destroyed, as the colonial powers pitted tribes against one another (Bates, 2012). Rather than overtly establishing discord among their subjects, a favorite ploy was to incite jealousy and envy by showing favor to some tribes but not to others, and arbitrarily installing chiefs who were manipulated to oppress and suppress other ethnic groupings. This sowed seeds of bitterness and anger in the foundations of many future nations, set the stage for intra and international conflict. Besides separating indigenous ethnic groups, colonial powers totally discouraged interclan interactions, creating prejudices by fostering tribalistic attitudes based on incorrect perceptions of others. A poignant example of this strategy was the apartheid regime in South Africa, which ended in 1994. Although the move to democracy was relatively peaceful, the country is now beset by internecine strife, which threatens economic and social development. Despite escaping the SAPs, the majority of black people in South Africa continue to live in squalor and suffer the indignities of poverty like those in many sub-Saharan countries.

Freedom movements arose in response to colonialism. National groups were established and nations came together across the continent to form the Pan-African Movement. The impact was massive, creating a domino effect of newly formed states. As colonial powers pulled out, a new era was born, with the Organization of African Unity being formed in 1963 by 32 member states. This became known as the African Union in 2002.

The fairy tale of an independent Africa was short lived. An unfortunate consequence of this historical process was that the prejudices that had been created and exploited under colonialism did not disappear overnight, but continued as 'bones of contention' within and among newly formed nations. This was seen during the genocide that took place in Rwanda in 1994 (Semujanga, 2003), which led to the massacre of more than 800 000 Tutsi men, women, and children, and the displacement of hundreds of thousands more. At the root of the genocide was the belief that Tutsi people were flaunting and abusing the historical favor they had gained from Belgian colonial masters, having carried the attitude of superiority into the postcolonial era to the disadvantage of the Hutu people (Des Forges, 1999; Adedeji, 1999; Semujanga, 2003).

Immediately after independence, young nations on the continent thrived. Wealth and investments flowed in liberally and spent without accountability including in the public sector. During such economic prosperity, albeit based on primary commodities, there was money to spend. Lack of scrutiny of government spending began a trend of resource abuse that opened the door to corruption (Wrong, 2009). Millions of aid money went into the pockets of a few in leaders such as heads of state who plundered state coffers with impunity. Their insatiable greed was described as pathological (Wrong, 2009).

As corruption grew politics became dirtier, the chasm between rich and poor people widened, and economies spiraled downward at breathtaking speed. The drop in commodity prices, the failure to produce adequate food, and concomitant inability to service accumulating debt and cope with growing inflation added to the rapid free fall of many sub-Saharan economies. Only certain groups of people were benefiting economically and many people had been better off at independence than afterward. Ideals such as national unity and a common identity were dismissed, and a mad scramble to gain resources, through whatever means possible, gained momentum. Notably, corrupt rulers of the new political dispensation took away power from traditional authorities and structures to make people powerless (Gibbon et al., 1992). Instability spread across the continent. Conflicts began as warlords and politicians attempted to bend the masses to their will. Again, it seemed that, at the root of the political instability that ended in conflict were corruption, tribalism, and xenophobia (Wrong, 2009). Those in power were intent on taking advantage of the remnants of colonialism to spur people on to war. A pattern was established: instability led to conflict, which caused further deterioration in stability, and led to more conflict as people fought to survive. DRC, Somalia, Mali, Sudan, and Uganda are examples of ongoing hostility and ethnic tensions causing people to flee for their lives, while warlords amass wealth and exploit the region (Gettleman, 2010; Adedeji, 1999).

Structural Adjustment Programmes

This context of widespread prejudice and misrepresentation on a continental scale calls for debate on African development that lacks a monolithic approach, which focuses entirely on economics. Unfortunately, various scholars (Campbell and Loxley, 1989; Gibbon, 1995; Devarajan et al., 2001) have expressed a neocolonialist mind-set that prescribes the one-size-fits-all solutions inherent in the SAPs. SAPs are "a set of free market economic policy reforms imposed on developing countries by the Bretton Woods institutions: the IMF and the World Bank in the 1980s and 1990s … as a condition for receipt of loans" imposed on almost all sub-Sahara African countries (Gibbon, 1995; Savas, 1987). This led social welfare programs to plummet from massive budgetary cuts in social funding resulting from the

economic financial crisis that affected almost all sub-Saharan Africa.

The financial crisis on the continent worsened from the 1970s to the 1990s, causing the social welfare of millions of people to decline to the lowest level ever. According to the Human Development Report (2012), many countries in sub-Saharan Africa ranked low in the Human Development Index, combined with poor measures in human capabilities regarding health, education, and income (p. 16). The inability of many families to acquire food due to lack of agricultural input and disposable income meant millions of people in the region experienced food insecurity at household and personal level, and weakened health status from poor nutrition. In sub-Saharan Africa, 31% of the population was undernourished in 1990–1992 (UN, Millennium Development Goals Report, 2012b). In 1990, over 29% of children under age five were either moderately or severely underweight (UN, Millennium Development Goals Report, 2012b). Hungry children suffer from communicable diseases that are ordinarily preventable and treatable and succumb easily to death. The result is high infant mortality rates. Children in sub-Saharan Africa tend to join school late and drop out early. Malnourished expectant mothers in rural areas far from health facilities face the prospect of death while giving birth. Agricultural production is hampered by ill-health from malnutrition and diseases such as HIV and AIDS, malaria, and tuberculosis, which impact negatively on food production. All these factors feed into a vicious circle of poverty, which has scaled down in other parts of the world, but spiraled out of control in sub-Saharan Africa (Khumalo, 2009).

At the same time, the economic crisis escalated as a result of a burgeoning external debt burden, the brain drain, capital flight, poor balance of payments, rising unemployment, infrastructure deterioration, growing budget deficits, inability to service internal and external debts, social inequalities, rampant inflation, negative interest rates (Ajayi and Khan, 2000) and corruption. Unequal terms of trade contributed to poor growth and caused the continent to become marginalized on the world trade stage and entrenched its position vis-a-vis lack of investment, negative growth, and poor economic performance (Adedeji, 1976, 2002). Dearth of investment in sub-Saharan Africa affected its capacity to export and caused the region to rely primarily on imported goods and services, turning these countries into net importers. The option for salvation, claimed the IMF and World Bank, was for sub-Saharan African nations to encourage a liberalized economic approach that would bring about growth and prosperity in both the short and long terms. The major thrust of the approach was based on growth of the economy, which, it was assumed, would eventually trickle down to deprived groups, including rural poor people. However, before that could happen, the state had to find money to launch a program of economic recovery. Without other ways of paying for it, many sub-Saharan countries were forced to seek financial assistance from the World Bank and IMF as the only source of funding (Gibbon, 1995; Devarajan et al., 2001). Funding came with conditionalities, including strict adherence to the adoption of the market economic model with private sector driven and free-market policies. Without other feasible options, the countries of sub-Sahara Africa were coerced into contracts for loans (Campbell and Loxley, 1989). This led many economies in the region to lose the ability to reorganize and relaunch their development agendas. The scarcity of capital and lack of adequate domestic savings ability led to financial chaos and economic collapse owing to hyperinflation, high unemployment rates, and lack of net investment for growth and development. The balance of payments could not be serviced and accumulated into huge debt, which over time, grew into an interminable debt burden (Ajayi and Khan, 2000). The concomitant offshoots of the crisis included severe shortage of goods and services and general hardships especially diswelfare and falling standards of living. The burden was heavier for rural areas than urban ones.

The SAPs, as a model of economic recovery based on free market economic policy reforms, consisted of a series of measures that had to be accepted and strictly adhered to by debt-burdened African countries to obtain loans. SAPs were applied to every country in Africa, regardless of its historical, cultural, and material circumstances or particular country context. These SAPs consisted mainly of the following components:

1. Elimination of subsidies
2. Reduction of public expenditure on social services
3. Devaluation of national currencies coupled with foreign-exchange auctions
4. Reliance on free market forces
5. Privatization of public enterprises
6. Liberalization of trade and inputs
7. Downsizing of the public labor force

(Adedeji, 2002; Chikulo, 1997; Gibbon, 1995, 1993).

The situation is akin to the contemporary phase of economic crisis being experienced in Southern Europe with consequences of extreme reduction in social spending and uneven distribution of incomes (Dominelli, 1990, 2010; Martin, 2012; Papadopoulos, 2012). There is total agreement about the economic crisis that engulfed the economies of sub-Saharan Africa and need to carry out reforms to resolve the crisis. However, disagreement arose over the particular model of economic recovery that had to be implemented. While some observers contend that SAPs were a necessity, others argue the contrary, and categorically believe that another credible alternative could have been implemented to address the continent's economic problem. SAPs were based on nondemocratic and unwarranted harsh methods without regards to the human aspect of development, which led to underdevelopment as is currently occurring in Southern Europe. For example, the UN Economic Commission for Africa provided an all-inclusive and sound alternative to SAPs in 1989 (Adedeji, 2002). This essentially offered an approach to development that considered the plight of humans. Another example was the African Alternative Framework, which called for 'Adjustment with transformation'. The emphasis in these and similar models was on reducing the continent's reliance on external trade and financing, fostering food self-sufficiency, and promoting popular participation in economic planning and decision making.

These all go against the imperialist expectations of the Bretton Woods institutions, their ideology and philosophy as Ioakimidis argued regarding Southern Europe (Ioakimidis, 2011).

SAPs' focus was supposed to correct the economy but it ended up finding new sources of capital accumulation for multinational corporations who initially used the state apparatus in their countries of origin to secure the conditions that suited them. Thus, insufficient attention was paid to the social consequences of the proposed economic growth model with the introduction of free market enterprise to 'eliminate trade and investment regulations', improve foreign-exchange income, increase exports, and reduce domestic borrowing and expenditure on subsidies and social welfare. Despite the harsh conditions imposed by the IMF and the World Bank, countries had no choice but to take the loans and strings attached. Many donor countries tied their aid to the adoption of the SAPs (Devarajan et al., 2001; Jordan and Drakeford, 2012). The World Bank and IMF were adamant that the SAPs were necessary to bring about economic development and recovery with the usual 'trickle down' theory, which continued to have appeal (Jordan and Drakeford, 2012). In retrospect, the SAPs constituted a project doomed to failure even before it was implemented as argued by many observers (Adedeji, 1999: pp. 521–522, 2002; Dominelli, 1999; Campbell and Loxley, 1989: pp. 1–3).

The countries of Africa were trapped for long periods in a never-ending debt repayment process through which the Bretton Woods institutions ensured rescheduling that enabled the arrangement to continue. The debt servicing design became the order of the day with a constant rise in rates of interest, which Onimode (1987) termed a 'Ponzi scheme' or fraudulent scam. Payments from debtor nations boosted domestic profits and made possible employment creation for the lenders while indebtedness, unemployment, and poverty in the debtor nations grew by leaps and bounds (Onimode, 1987: vol. 2).

Despite the immense, growing burden caused by the SAPs, the IMF, World Bank, and creditor nations remained oblivious to the harsh economic hardships of poorer countries. This led to global outcry by organizations, individuals, activists, political leaders, the church, and Jubilee 2000 (http://www.guardian.co.uk/global-development/2011/nov/15/vulture-funds-jersey-decisions; Carrasco et al., 2007) that felt that the debt had caused untold misery among children, women, and older people. Women and children, with their vulnerable socioeconomic positions, bore a disproportionate share of the burden created by SAPs (Mupedziswa and Gumbo, 1998). The world's conscience through leading figures, the Jubilee 2000 Movement and Jeffrey Sachs (www.sgiquartely.org/feature/2000Jly.5html), and Greene and Khan (1990) spoke out about the negative aspects of SAPs and made a determined effort to spearhead the cancellation of debt to give the ailing economies of sub-Saharan Africa an opportunity to recover. However, extreme poverty affected millions of people in the region as economies continued to experience deep recession. The absolute number of people living in extreme poverty reached 395 million in 2005 but dropped to 386 million by 2008 (a 5% reduction), while other regions demonstrated significant reductions in poverty. Nevertheless, the majority of people in sub-Sahara Africa continue to live below the absolute poverty rate of $1.25 a day (Millennium Development Goals Report, 2012b). For those in rural areas, or places of conflict, the debt burden was disproportionate. They faced crumbling infrastructure, lack of food security, relentless poverty, unemployment, and the devastation of diseases such as HIV and AIDS, tuberculosis, and malaria. They were confronted daily by declining life expectancy, unacceptably high rates of maternal and child mortality, and famine; while a few lived in unimaginable luxury, funded through ill-gotten gains, usually in urban areas or abroad. While the donor countries forgave the highly indebted countries by dropping the demand to pay any outstanding debt, nobody knows the extent of the negative impact of the SAPs and concomitant injury caused to the people of Africa. The African situation may sound outdated but should alarm Southern Europe. The crisis will be long and hard with consequences of rising unemployment, budgetary austerity, slowing of domestic economy, growth deficit, and a deterioration in living standards for majority of citizens (Das, 2008; Martin, 2012).

Many groups including nongovernmental and humanitarian and grassroots organizations and churches saw through the actions of donor countries and lending institutions like the IMF and World Bank: the debtor nations were totally incapable of paying back the outstanding loans (Jeffrey Sachs, 2000). The debtor nations had more than paid back the original principal on the loans and the whole exercise of continued paying was a mockery by any standard. The situation led to worsening poverty outcomes and perpetual unequal relations thus entrenching inequalities and ever-growing gap between the rich and poor nations and individuals within sub-Saharan countries themselves.

SAP's schemes led to the emergence of a new form of inequality between debtor and donor nations. Previously the parties had comprised the colonizers and colonized – a correlation, which ended at the time of independence when the countries of sub-Saharan Africa attained sovereign statehood. The new relationship, however, consisted of debtor and creditor countries. This relationship ushered in a new form of colonialism, which essentially ensured continuation of the domination of social, political, cultural, and economic relations by former colonial masters. Although Nkrumah (1965) warned of such a relationship as neocolonialism and imperialism in which former colonial powers continued to maintain control or hegemony over former colonized countries and thus perpetuate colonialism in a new form, the issue has gone beyond this in the last few decades. Like in Southern Europe, the rise of large multinational corporations that have more economic clout than nation states and the rise of China as a global economic player has made Western governments play into the pockets of financial elites who are unaccountable to none but themselves (Dominelli, 2009). This situation has led multinational corporations to act with impunity in their fraudulent activities throughout the globe to maintain their influence. Essentially, apart from Botswana, Mauritius, and South Africa the countries of Africa have become locked into new forms of independent/dependent relationships with Western governments and financial institutions. The unequal relationships imposed on

these countries have undermined their sovereignty and virtually crafted them into marionettes of the West (Campbell and Loxley, 1989; Onimode, 1987). The end of the Cold War has not substantially altered these political and economic dynamics because developed countries continue to use methods of control over African countries. The entry of China on to the global scene has not changed these power relations, but worsened the situation for African countries (Heller, 2006; Ghosh, 2006).

Implications for Social Work Practice

The first implication for social workers wishing to depart from neocolonial relationships is that social work must be redefined to fit the realities of Africa. The need to reconfigure African societies' structures and economic functioning has grown exponentially over the past quarter of a century. The African continent demands a corresponding realignment in the social sciences and social work practice. This is particularly evident in social work, addressing, as it does, social functioning at individual, familial, and societal levels. International conceptualizations of social work focus on these three levels with, ostensibly, equal emphasis. However, the reality is that people in the developed world are tending to become more and more isolated and individualistic and social work practice is increasingly responsive to this phenomenon. Thus, although the consensus is that person in environment is the mantra for assessment and intervention, reality is not always in line with this contention (Dominelli, 1999, 2002; Mullaly, 1997).

Social work practice should identify its inherent purpose in relation to the needs of vulnerable, marginalized, and minority groups in society and work toward social justice for all. Also important is for a definition of social work in Africa to incorporate a common point of departure. The community would serve well in this regard as it situates the practice within an environmental perspective demonstrating the fundamental and traditional importance of kinship systems and other social structures of value in daily life (Dominelli, 1999, 2002; Mullaly, 1997). This also recognizes that social issues in Africa are essentially community issues that cannot be effectively dealt with by focusing on individuals without acknowledging that society, family, and individuals are essential elements of a coordinated approach to social work practice. Such issues have to be incorporated in a universal definition of social work and its practice if the needs of all peoples are to be addressed adequately.

In Africa, like elsewhere, care has to be taken to ensure that social work takes cognizance of culture and related environmental factors as populations are integrated into these aspects of life. Although individualistic trends are becoming more apparent, the situation on the ground is bound up with societal and familial expectations. Manipulating the relationship between development and custom calls for special skills in social workers and these have to be incorporated into Western definitions and theoretical frameworks for practice to avoid neocolonial relationships.

Secondly, in searching for the appropriate implications of social work in Africa in current global and regional economic trends and demands, social workers worldwide must continue to base their practice on the well-established principles and values of human rights and social justice while focusing on marginalized and disadvantaged peoples. Thus curricula changes to incorporate interventions that promote empowerment and strengths and human rights–based approaches (Mullaly, 1997) for sustainable development are required in programs. Empowering interventions are suitable and efficacious for sustainable development because they advocate equity and social justice in all development processes. The attraction of a human rights–based approach is that it ensures that human rights' values and principles distinctively guide the development and capacity of all stakeholders (Hardcastle and Powers, 2004; Midgley and Conley, 2010) and stimulates a consciousness and awareness of human rights in the process of working with various groups of people to resolve their problems. The human rights–based approach is also essential in realizing the Millennium Development Goals, the Convention on the Elimination of all Forms of Discrimination Against Women (CEDAW), and other global initiatives. Human rights relate well to globalization and neoliberalism in addressing the recent global financial crisis, which has demonstrated the interdependence among peoples of the world and carries implications for social work practice (Dominelli, 2013).

Professionals in Africa must constantly remember that the continent shares this rapidly changing and globalizing environment. Hence, continuously developing the profession's standards, principles, methods, and skills base in relation to the specific challenges experienced on a daily basis is important. In the African context, challenges of practice include highly disparate levels of socioeconomic development, widespread and complex conflicts and wars, large-scale poverty, and a ravaging HIV and AIDS epidemic. To develop responses that are locally relevant and appropriate, it is important to draw on existing local knowledge, skills, and value systems. These are strengths to be incorporated into a profession seeking to make a meaningful contribution to social and economic development in Africa.

The focus of practice in Africa, as elsewhere, must be to develop strategies for capacity building among people to free them from control and oppression. Control and oppression have pervasive effects on the lives of people and undermine the value base of social work regarding personal dignity and worth, egalitarianism, social equality, and democratic ideals (Mullaly, 1997). This is why community practice approaches that emphasize economic development, physical environment, and those models that critique models of capitalist models of socioeconomic development must be promoted as engines of practice through models incorporating social action and planning (Zastrow, 1993; Shragge, 1997; Sherraden and Ninacs, 1998; Hardcastle and Powers, 2004; Ambrosino et al., 2005; Zapf, 2010).

Conclusion

Economic crises have happened in many parts of the world but, as Carol Lancaster has observed, "the economic crisis in Africa has involved problems much deeper than those posed by

short-term financial obligation" (1983: pp. 149–150; De Menil, 2012). Lancaster made these remarks in relation to the debt crisis then taking place in Latin America. Africa's economic crisis is indeed multifaceted, complex, and structural, which cannot be explained unilaterally, whatever the attractions of that view. The observers (Nissanke, 2003) of the African phenomenon should exercise patience and caution in theorizing its nature and origins, attempting instead, to examine a plethora of circumstances some of which are historical and intricate. I do not disagree that there has been a crisis and intervention was necessary to resolve it. However, the question has always been: could there have been an alternative to the SAPs imposed by the IMF and World Bank? The liberal perspective enabled SAPs to impose free market enterprise models that ushered in new forms of relationships between the indebted and lender nations that perpetuated old power relationships embedded in colonizer and colonized binaries and created new relationships that produced a new order or form of colonialism popularly referred to as neocolonialism. The SAPs created more hardships among people as unemployment, poverty (with its offshoots), higher infant and maternal mortality rates, and unprecedented levels of illiteracy. Social work, as professional practice based on principles of humanitarianism and social justice, must adopt strategies and approaches that liberate marginalized and disenfranchised populations. This can be achieved through a redefinition of its purpose to reflect the unique circumstances of the African continent.

Structural Balance Theory: Recent Developments

Peter Abell, London School of Economics, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Structural balance analyzes the statics and dynamics of signed graphs (digraphs), which experience stress induced by cycles with an uneven number of negative links. The theory postulates two alternative equilibria (balanced states), either k-sets of (predominately) positively related nodes separated by negative links or a single set of positively linked nodes.

Introduction

Structural balance theory concerns the formation, dynamics, and ultimate stable (i.e., balanced) disposition of positive (P) and negative (N) expressive pairwise binary relations/links on a finite set (n) of actors, which may be individuals or collective entities. Friendship and enmity provide typical examples of expressive relations; though the theory covers any type of relationship carrying positive and negative emotional orientations, it has in addition been extended to trust and mistrust relationships. Although the theory has been applied predominately to small groups of individuals, relations between nations have also been explored.

The structures generated by the relations on n nodes can be depicted as either signed graphs, G(n;P,N), where the relations are symmetric (reciprocal) or digraphs when the relations are directed. Directed structures are usually generated by studies of individual choices and symmetric structures when the focus is upon sustained reciprocal relationships. The pairwise relations/links/edges are conveniently labeled as either $+1$ or -1. Correspondingly, they can also be depicted as the associated incidence matrices (M). The theory can be extended by allowing the links to be weighted; either normed in the interval -1 through $+1$ or drawn from a continuous distribution on the real line. The entries in M are then adjusted accordingly. Reflexive (self) relations are sometimes introduced usually for mathematical purposes. Occasionally, 'ambivalent' relations have been suggested whereby both a positive and a negative link can exist between two nodes (symmetric links implying mutual ambivalence and directed links implying unilateral ambivalence).

Origins and Development of Balance Theory

The theory of structural balance developed from Heider's (1946) exploration of an individual (p) with negative- and positive-directed orientations to both another individual (o) and simultaneously to objects/concepts (x), with (o) also having a signed orientation to (x). It is further assumed that (p) is aware of the orientation of (o) toward (x). The links to (x) were denominated as 'unit formations.' Eight types of possible, so-called 'pox' triples, centered upon (p) are then possible. It was assumed that only those triples with an even number of negative links are stable (balanced), the others induce stress, which will in due course be resolved by the change of sign of a link that was left undetermined.

Cartwright and Harrary (1956) extended this basic picture to incorporate interpersonal relations across many actors, leading to graph-theoretic depictions of signed structures. In the process the orientation to objects was lost, though more recently objects have been reintroduced within the framework of bipartite graphs (Mrvar and Doreian, 2009). Graph-theoretic depiction introduced the distinction between symmetric (reciprocal) and directed links. Early empirical studies of the signed structures tended to consider small groups with complete structures where all the pairs of nodes/actors are directly linked to either P or N (symmetric or directed). More recently, incomplete structures have been incorporated in attempts to apply the theory to larger structures. Incompletion allows for unlinked (null) pairs, which may be either unacquainted or entertain a 'neutral' affective orientation. In the former case the sign of the link is fixed at null (up to the formation of a new link) whereas in the latter case the link can subsequently acquire a value (P or N). These distinctions have not been systematically incorporated into the theory, though the relative density of P, N, and null links plays a role in recent developments.

Balance Theory

The standard assumptions (axioms) of balance theory are often colloquially expressed in terms of friendship and enmity, which give a direct pointer to the intuition behind the theory. So, stable (i.e., balanced) situations run as follows:

1. A friend of a friend is a friend,
2. An enemy of a friend is an enemy,
3. A friend of an enemy is an enemy, and
4. An enemy of an enemy is a friend.

In the context of incomplete structures, however, a slight reformulation better expresses stable situations:

5. A friend of a friend is not an enemy (i.e., is a friend or null),
6. An enemy of a friend is not a friend (i.e., is an enemy or null),
7. A friend of an enemy is not a friend (i.e., is an enemy or null), and
8. An enemy of an enemy is not an enemy (i.e., is a friend or null).

It is postulated that those involved in a particular imbalanced 3-(semi)cycle (with either directed or symmetric links) experience stress and consequently seek to remedy the situation by either deleting or changing the sign of one of the offending links (thus, by either eradicating imbalance or inducing balance).

In the case of weighted links the state of balance of a cycle (or directed triple) is computed by the product of the weightings. However, Montgomery (2009) underscores the fact that imbalanced triples only induce stress if individuals are aware of the nature of the links between others (or from others to concept (x) in the case of 'pox' triples). Thus, it is only with complete awareness (which is often an unrealistic supposition in large structures) that imbalance implies instability.

It is usually assumed that structures do not evolve according to the precepts of balance but rather by the random creation of links, thus initially acquiring imbalanced cycles, which then subsequently adjust toward balance with the passage of time. Since links in the graph G(n;P,N) are involved in up to $(n - 2)$ 3-cycles in a complete structure, it becomes a matter of detailed calculation as to what the impact of changing the sign of a particular link would be. The dynamics are consequently often left undetermined. In this respect the tendency toward balance/stability is treated not unlike many equilibrium theories, which remain silent about the inherent complexities of the off-equilibrium dynamic path.

Nevertheless, the global balance of a structure can be followed by a number of possible coefficients each of which is applicable to both directed and symmetric links, though the counting procedures have to be adjusted accordingly. A line index gives the number of links, which need to flip sign or, equivalently, be deleted in order to attain balance. An alternative is to compute the proportion of balanced 3-cycles ($\beta(3)$) at any particular juncture. The node balance ($\beta_i(3)$) and link balance ($\beta_{ij}(3)$) can likewise be defined in terms of the proportion of balanced cycles subtended by respectively node, i and link, ij. These coefficients can easily be extended to compute the proportional difference between the balanced cycles and their random expectation, given the proportion of P links. Alternatively, the stress is expressed as $(1 - \beta(\cdot))$. A logically equivalent conception (deriving from physicists who have taken an interest in balance) is to interpret stress as potential energy (PE) and the move to balance minimizes the PE. Then, in a complete structure, $(PE) = -Tr(M^3)/{}^nC_3$, acquiring a value of -1 at balance.

The various methods of tracking balance/stress can be extended to incorporate weighted P and N links, which are usually allowed to vary between -1 and $+1$, though recently dynamic models (below), which allow for indefinite continuous scaling, have been introduced.

In a complete structure with symmetric links counting the 3-cyles is equivalent to counting cycles of all lengths. A complete balanced structure will contain no cycles of any length with an uneven number of negative links. But this is not so with incomplete structures, which may contain longer imbalanced cycles and no imbalanced 3-cycles. It is possible then to compute $\beta(n)$ rather than $\beta(3)$, which embraces cycles of all lengths. Although incorporating longer cycles into balance theory is often necessary to maintain its mathematical precision, whether long cycles induce stress remains controversial.

The Structural Theorems

A complete balanced structure G(n;P,N) will, according to the First Structural Theorem (Cartwright and Harary, 1956), comprise either a single set (group) of P-linked nodes or two such sets (groups) connected by N links (bipolarization). It is this theorem which has given balance theory much of its prominence by providing a potential theory of subgroup formation in signed structures.

It leaves open, however, the conditions under which balance will surrender either a single or two groups. In addition, though balance theory has largely been treated as deterministic, the issue arises as to how tolerant near-balance is to the presence of a small numbers of imbalanced 3-cycles. A theorem due to Easley and Kleinberg (2010) states: In a complete signed graph with at least $(1 - e)$ balanced 3-cycles where $0 \leq e \leq 1/8$ and $d = (e)^{1/3}$, then either at least $(1 - d)$ of the nodes are linked by at least $(1 - d)$ of positively related pairs (approximate unity) or the structure consists of two groups where at least $(1 - d)$ pairs are positively related in both groups, and at least $(1 - d)$ pairs are negatively related between the groups. So when $e = 0$, we recover the first structural theorem but note that balance falls away strongly as e increases.

Incomplete but connected structures will probably contain null links in a unified group or both within and between the polarized groups. In this respect the densities of P and N links within and between groups become the focus of attention.

Davis (1967) proposed that all negative 3-cycles (triples) may well be relatively stable. The Second Structural Theorem, incorporating this assumption states that: a k-balanced structure will comprise of either a single or a number, k, of positively related node sets (groups), again, in the latter case each negatively linked.

We can, thus, speak of k-balance, where $k = 1$ or 2 when all negative 3-cycles do contribute to imbalance, and potentially $k > 2$ when they do not. The terms 'clusters' and 'plus sets' referring to k-sets are to be found in the literature.

The instability of 3-cycles with one negative link has also been questioned on the grounds that they can provide a functional bridge between conflicting nodes. If both all negative and one negative 3-cycles were to be deemed stable (stress free) then balance theory would fail. These considerations prompt the notion that thresholds (see below) may operate in respect of the instability of different 3-cycle types.

Statics: Studying Balanced and Near-Balanced States

Since (k)-balance theories predict the evolution of a variety of alternative possible balanced (stable) states, recording the comparative equilibrium statics becomes of central importance. Visual inspection of small structures gives way to formal procedures as n increases and near k-balanced states, particularly in incomplete structures, also enter the picture.

Network block-modeling techniques, which involve permutations of the rows and columns of the appropriate incidence matrix, M, have been extended to incorporate signed links for both one- and two-mode networks (Brusco et al., 2011). In the latter respect, Heider's unit relations are reintroduced into the theory (Doreian and Mrvar, 2009). Balanced

states are located by finding a permutation on M, which locates blocks of positively (and null relations in incomplete structures) related nodes down the leading diagonal. The algorithms minimize the number of misplaced links (i.e., negative links (weighted or binary) internal to the k-sets and positive ones between them). Other mechanisms like differential popularity/unpopularity (thus, degree power laws) can interfere with the likelihood of finding clean k-sets. Relaxed Structural Balance (Doreian and Mrvar, 2009) allows for an approximation to an equilibrium at k-sets within the framework of block modeling by disturbing the neat pattern in any permutations on M and also introducing the possibility of mutually negative nodes (negative blocks). The two structural theorems are then special cases of the more general theory. Although methods of extracting pictures of near-balanced structures are now well developed, balance dynamics that introduce probability in accounting for the variety of outcomes have not been explored. Furthermore, since the time line of stress-reducing dynamics is little understood, whether or not a particular empirical structure has come to rest is often by no means clear.

Dynamics: Studying Adjustment toward Balance

Since more than one stable state is predicted by k-balance theory it cannot be regarded as complete without a specification of how the alternatives arise. It is only recently that the complexities of possible dynamics have been addressed and the literature is, so far, confined to $k = 2$ theory.

If complete structures were to evolve in accordance with the precepts of $k = 2$ balance then the proportion of N links would be maximized and P links minimized (both at 0.5) at $k = 2$ equal-sized groups. The proportion of negative links would fall to zero as a single ($k = 1$) group forms. The dynamics would be determined by the proportion of positive and negative links created at the early period of the evolution and balance would determine the transitive closure of 3-cycles. However, only a few studies conceive of balance in this respect (which would require actors to anticipate stress and, consequently, not to establish imbalanced cycles) but rather assume that stress develops over time in already established imbalanced cycles. Thus, balance is usually construed as an adjustment mechanism in structures that have evolved under the impact of other mechanisms. If P and N links are assigned randomly the probability that a balanced network would form decreases exponentially with n. Current lines of research, however, seek to understand the evolution of signed networks under the impact of multiple mechanisms (e.g., small world and scale free) including balance.

Doreian and Krackhardt (2001), studying transitive closure with directed links, found that adjustments eventuating in PPP, PNN, PNP, and PNP cycles were all consistent with balance, the first two increasing and the latter two decreasing over time, whereas the remaining types were not; NNN increased consistently with $k > 2$ balance.

The dynamics of both binary and weighted models have been studied combining a mixture of simulation and analytical results in both discrete and continuous time. The starting point is usually a structure with randomly distributed varying initial proportions of positive and negative links (sometimes null links also and thus varying density); n is usually fixed, though some analytical results as $n \rightarrow$ infinity have been established.

Queries arise as to whether and the extent to which balance adjustment depends upon the structure size (n), the initial proportion of P, N, and null links (thus density), the relative propensity of P and N links to change sign, and above all, the precise nature of the adjustment mechanism. In the last respect it is important to contrast 'local' mechanisms, which make only limited demands upon an actor's cognitive capacities with 'global' mechanisms, which assume a capacity to assay all the cycles in which an actor is involved.

Antal et al. (2005, 2006) showed that complete structures with binary, symmetric links, adjusting in discrete time, can sometimes fail to reach either of the balanced states, becoming 'jammed' while still imbalanced. Nevertheless, simulations of a local adjustment rule which allows that a randomly selected imbalanced 3-cycle flips the sign of a constituent link, without any regard to the impact on other cycles can procure $k = 1$ balance when the probability that an N link flips to P in one negative 3-cycles is greater than 0.5. If the 'local' adjustment rule is replaced by a 'global' one which selects a link at random and changes its sign only if this decreases the number of imbalanced cycles in the structure, then a sharp transition from $k = 2$ to $k = 1$ balance occurs when the initial proportion of P links is about 0.6. The transition is invariant to a large range in n.

Kulakowski et al. (2008) allowed for weighted links (normed between $-R$ and $+R$), continuous rather than discrete time and global adjustment, enabling a simple differential equation treatment of balancing dynamics. They showed (by simulation) that the time to balance falls with both the size ($n^{-1/2}$) of the network and R (up to $n = 500$). Further, by increasing the initial proportion of P links, a sharp transition from convergence at polarization to convergence at unity is encountered. Balance is always attained and persists.

The continuous time model with global adjustment was further developed by Marvel et al. (2011) providing closed-form demonstration that, over a wide range of initial conditions, balance is necessarily achieved in a finite time; polarization or unity occurs depending on the initial proportion of P links, a result supporting the earlier simulations. However, the dynamics conceived as $dM/dt = M^2$ in complete structures generate a divergence to infinite values for the link weights, though balance is achieved prior to this divergence. Nevertheless, the values required at balance are unrealistic and whether this is pertinent to empirical investigation remains an open question. The authors opine that other mechanisms may be signaled, when large weightings occur, which also drive toward balance.

Abell and Ludwig (2009) combine the growth and balance adjustment of network rather than allowing balance to operate upon an exogenously given structure. They also allowed nodes to tolerate imbalance up to a varying threshold and studied, by simulation, a model where varying proportions of symmetric P and N links are introduced to a node set and any induced imbalance is subsequently solved by cascading the deletion of offending links. The distribution of the sizes of the cascades was reported. Simulations in the space generated by allowing both the threshold and proportion of P links introduced to vary, demonstrate sharp transitions in the degree of balance

achieved and completion at a steady state. One of the regions in the space exhibits power-law distribution in cascade sizes perhaps characteristic of self-organized criticality.

Deng and Abell (2010) studied local ('myopic') balance adjustment as a Markov process with varying transition probabilities between the four types of 3-cycles. The density of links (d), initial proportion of P links (α), network size (n), and transition probabilities were also allowed to vary. The convergence to balance depends critically upon the transition probabilities. Local adjustment does not generate balance but a steady state where $\beta(3) = 0.5$, unless the transition probabilities reflect a strong bias toward P links, when $k = 1$ is favored (cf Antal et al., 2005). This result is immune to variations in a range of network sizes ($n > 30$), densities ($d > 0.3$), and initial proportion of P links ($\alpha < 0.9$). However, below these various parameter values the balance outcome exhibits marked fluctuations, which suggests that the outcomes of small-group studies, which support balance, must involve a global adjustment. Different combinations of 3-cycles were allowed to operate as attractors to explore $k > 2$ balance theory.

Our current understanding of balance dynamics is far from comprehensive. Controlling for other possible conflating mechanisms and possible thresholds, do signed structures achieve balance and if so at which value of k? Analytical results demonstrate that global adjustment will achieve balance in complete structures ($k = 1$ when the initial proportion of P links $\alpha > 0.5$, $k = 2$ when $\alpha < 0.5$) but for incomplete and more realistic local adjustment the picture is more ambiguous. This ambiguity is, however, in accord with accumulated empirical evidence.

Recent Empirical Support

Although recently claims have been made for the predictive capacity of balance theory using very large data sets (e.g., Szell et al., 2010), empirical studies have over the years been dogged by many problems. Paramount among these have been the paucity of longitudinal studies, the difficulties encountered in the identification of negative links, and the interaction of balance with other mechanisms which all appear to have different adjustment time scales. Furthermore, the social context in which the adjustment occurs can have a profound impact (perhaps by virtue of exogenously varying thresholds). At the individual level a small number of data sets (often not designed to address balance issues) have been mined and repeatedly reworked. Recently (Doreian and Mrvar, 2009), two-mode analysis has been applied to voting patterns of the Supreme Court (USA). Balance has proved effective in the analysis of polarization in international relations (Antal et al., 2005). Guha et al. (2004) extended $k = 2$ balance theory to trust- and distrust-directed relations inviting a theoretical connection between balance and game theory. Nevertheless, the parallel between positive and negative affect and trust and distrust has to be handled with considerable care.

The current conclusion which may be drawn from the empirical literature is that balance is often a detectable adjustment mechanism operative in otherwise generated affective structures at varying scales. There is little evidence, though that complete polarization into two or k plus-sets is a universal phenomenon suggesting that local adjustment is often operative. However, in structures with either a high initial proportion of P links, or a disproportionate propensity for P links to form, (which may in practice correlate) approximate adjustment to one set is probably more assured (also supported by both simulation and analytical studies in both continuous and discrete time). In the future, balance dynamics will be studied under the auspices of local adjustment but accompanied by other mechanisms. As it appears that the distinction between local and global adjustment appears so crucial, one may anticipate studies of dynamics with adjustment lying between these extremes.

Structural Contingency Theory

Lex Donaldson, School of Management, UNSW-Business School, University of New South Wales, Sydney, NSW, Australia

Abstract

Structural contingency theory holds that the effect on organizational performance of organizational structure depends upon how far the structure fits the contingencies, such as uncertainty, strategy, and size. Organizations facing low uncertainty are fitted by specialized and centralized hierarchical structures, whereas organizations facing high uncertainty are fitted by lower specialization and decentralization (i.e., decisions being taken at lower levels of the hierarchy). Undiversified strategy is fitted by a functional structure, whereas diversified strategy is fitted by a multidivisional structure. Larger size is fitted by more specialized and decentralized structure. Various changes over time in focus are identified, such as from differentiation to interdependence.

Definitions

Structural contingency theory is a theory about how an organizational structure needs to fit factors, such as its strategy and size, in order to produce high performance. These factors are referred to as contingencies, because the performance resulting from an organizational structure is contingent upon how far it fits those factors.

Intellectual Background

Organizational structure refers to features such as the degree of specialization of roles in an organization, centralization of decision-making, and so on. Early attempts to prescribe effective organizational structures produced Principles of Management in what came to be referred to as Classical Management. This tended to prescribe structures that had specialized roles, detailed role definitions, standard procedures, and centralized, top-down structures. Subsequently this view was challenged by Human Relations Theory which prescribed loose role definitions and bottom-up structures in which lower level employees exercised relative autonomy or had influence on decisions. Structural contingency theory sought to resolve this tension by saying that each theory was right in its own place. Thus the optimal structure depended upon fitting the contingency factors.

For instance, where organizations faced environments low on uncertainty, they required top-down type of structures that were specialized and centralized (i.e., Classical Management); whereas, where organizations faced environments high on uncertainty, they required bottom-up type of structures that were low on specialization and were decentralized (i.e., Human Relations). This widely received branch of structural contingency theory was created by Burns and Stalker (1961).

Other important early advocates of structural contingency theory were Child, Galbraith, Lawrence, Lorsch, Perrow, Thompson, and Woodward. In particular, Lawrence and Lorsch (1967) described their approach as being a contingency theory. There had already been a contingency theory of leadership, but theirs was the first application of this term to organization structure. This became known as structural contingency theory. Structural contingency theory became the cornerstone of teaching in business schools about which structures are most effective in courses such as Organizational Design or Strategic Management, and is prominent in textbooks on such subjects to the present day, though not always called contingency theory. For a collection of milestone journal articles on research into structural contingency theory see Donaldson (1995).

Current Knowledge

It is convenient to consider there to be three major contingencies of organizational structure: uncertainty, size, and strategy.

The Contingency of Uncertainty

Uncertainty is the inability to predict what course of action will lead to the desired results because of unpredictable variation or lack of knowledge. The environment is a major source of uncertainty, but uncertainty can also arise from the task inside the organization. Much uncertainty comes from seeking to innovate in product or service, or from seeking to provide these in new ways (e.g., online). Burns and Stalker (1961) argued that when uncertainty is low, operations become routine and can be captured by rules that are specified from the top-down, while organizational roles are specialized and closely defined; this type of structure they call mechanistic. In contrast, where uncertainty is high, operations need to rely on the initiative of employees who view their role more broadly; this type of structure they call organic. Burns and Stalker view these two organizational forms as lying at either extreme of a continuum, according to the degree of uncertainty involved.

Lawrence and Lorsch (1967) argued that in predictable environments, departments would be similar, because all functional departments have high certainty, so they can all rely on rules and the like; hence they all tend toward being mechanistic. Therefore, there is little internal differentiation between departments. The differentiation within the organization being low, the organization requires only low levels of integration, such as meetings between members of the departments. In contrast, in unpredictable environments, departments would

differ, with production being certain and mechanistic and research being uncertain and organic, so that the differentiation within the organization would be high, requiring high levels of integration, such as by project teams.

The Contingency of Strategy

Structural contingency theory considers strategy in terms of diversification and vertical integration. A corporate strategy of low diversification is fitted by a functional structure in which the major organizational subunits are functions and their heads report directly to the head of the corporation (CEO). This fosters specialist expertise in each function, promoting efficiency. The functions are cost centers and the only profit center is the whole firm. The CEO can be involved in coordination of the functions, so that the structure is relatively centralized. However, higher diversification is fitted by a multidivisional structure in which the major organizational subunits are businesses, each of whose heads report directly to the head of the corporation (CEO). This fosters coordination across functions for serving particular products or customers. The CEO lacks detailed knowledge of all the divisions' operations and so the divisions are granted some autonomy and the structure is relatively decentralized. The more diversified is an organization, the more decentralized is its structure and so the smaller in size and functions the corporate head office needs to be. Similarly, with more diversification, rewards for subunit heads can shift from being based on corporate performance to being based on subunit performance.

Divisions need to be defined by whichever variable forms the highest degree of diversification: product, customer, or geography. Where more than one variable is quite high on diversification then a matrix structure becomes appropriate.

If corporate strategy favors more rather than less vertical integration, then the stages in adding value to raw material (e.g., mining, refining, and manufacturing) may each become divisions, but subject to central planning of production and transportation across the divisions. Thus, divisional autonomy needs to be restricted and the head office needs to be relatively large (Lorsch and Allen, 1973).

The Contingency of Size

Organizational size refers to the number of people in an organization. As size increases, the number of people reporting directly to the CEO becomes suboptimal, and so an intermediary management level is added. This process needs to be repeated as organizational size grows. Thus, larger size is fitted by more levels in the hierarchy. The greater complexity from increased size and hierarchy requires the top managers to delegate more decision-making. Similarly as size increases, work has to be divided between more people and so role specialization needs to increase, as does the number of departments. Larger size also makes administrative decisions routine, such as hiring, so that rules can be developed that allow faster and more effective decision-making. The structuring of work that comes from these increases in specialization and rules compensate for the increased decentralization, providing compensatory means of control by top management over lower level employees.

Changes in Focus or Emphasis over Time

From Single to Multiple Contingency Fits

Over time, structural contingency theory research has moved from considering one single contingency at a time to considering multiple, simultaneous contingencies. Early structural contingency theory research concentrated on making the argument that, rather than there being a 'one best way,' optimal structures were contingent upon fitting to some factor, e.g., technology (Woodward, 1965) or change in the organization's environment (Burns and Stalker, 1961). They tended to make the case for a particular contingency variable, such as technology or uncertainty. Some subsequent research has been concerned with empirically establishing that structure really is subject to such contingencies in its effect on performance or similar outcomes. This reflects anxiety that not all studies confirm the original contingency relationships, so that empirical validity of individual structural contingencies is still an ongoing concern in the research literature.

Child (1975), however, argued that both size and uncertainty were simultaneously contingencies of structure. And other research has sought to draw together multiple contingences as bearing simultaneously upon various aspects of structure. However, even after several decades, much of the research can be condensed into models in which about seven or so structural variables are each on average fitted to about two contingencies. Thus, fears that structural contingency theory must degenerate into bewildering complexity may be unwarranted.

In one particularly comprehensive synthesis, there are many contingencies which are considered to bear on many aspects of structure (Burton et al., 2002). This might seem to lead to the conclusion that managers have to attend to many simultaneous misfits of the multiple structural variables to the multiple contingency variables, rendering structural change complex. However, Burton et al. (2002) found empirically that the largest misfit accounted for much of the performance loss. Thus, while there can be many combinations of contingencies and structures that produce performance loss, managers only need to identify which is the main misfit in their organization to obtain most of the benefit to be had from changing the structure.

The Contingency of Technology?

While technology is the first structural contingency and pioneered the structural contingency approach its study has not fared well over the years. The pioneering researcher, Woodward (1965), presented sparse evidence of a link between fit and performance. While replication by others was claimed (Zwerman, 1970), this was disputed (Child and Mansfield, 1972; Donaldson, 1976). There have been attempts to maintain the idea of a technology contingency by changing the nature of the contingency or by arguing it exists only for parts of the organization (Reimann, 1980). But these have not been conclusive. Technology should be thought of as part of the research effort that pioneered structural contingency theory, but not as part of the established contemporary core structural contingency theory. This is important because the neo-institutional theory of organizations school gives as a reason for rejecting contingency theory that technology failed to be a useful contingency in their studies of educational systems

(Meyer and Scott, 1983). But if technology is not a core contingency of structural contingency theory its failure in that setting does not justify a rejection of structural contingency theory.

From Curvilinear to Linear Fits

The simplest fit of a structural variable to the contingency variable is that as the contingency level increases so too does the fitting level of the structural variable. Most research takes this simple, linear approach (e.g., Keller, 1994) and this may make the best theoretical sense for many fits of structural variables to their contingencies. However, the fitting structural level could have a curvilinear relationship to the contingency variable. Indeed the early depiction of a structural contingency relationship by Woodward (1965) shows that the level of the structural variable that has the highest performance first increases and then decreases as the technology contingency variable increases. The theoretical interpretation is that work initially involves skill and requires close supervision, but then mass production assembly lines entail less skill and supervision, while, finally, continuous production (e.g., oil refinery) has few highly skilled workers responsible for expensive, automated production systems. However, it can be questioned whether the apparent curvilinearity is anything more than sampling error in an otherwise linear relationship. Therefore, the use of linear, rather than curvilinear, fits of structure to contingencies may be justifiable.

From Differentiation to Interdependence

Initially, Lawrence and Lorsch (1967) proposed that organizations facing predictable environments only needed small differences between their functional departments and so only needed weak integration to fit (as explained above). In contrast, organizations facing unpredictable environments had larger differences between their functional departments and so needed strong integration to fit. Thus, differentiation must be matched by integration for high performance to result. This became known as the 'differentiation and integration (DnI),' approach. It held in their original study of fairly undiversified business firms, but in a later study of diversified corporations, there was no relation between the match of differentiation–integration and performance. This led Lawrence and Lorsch to reinterpret their findings in light of the theory of interdependence of Thompson (1967).

Thompson distinguished degrees of interdependence between parts of an organization: pooled where there was no direct connection, sequential where one part did its job before another worked on it, and reciprocal where work passes back and forth between two parts. He argued that pooled interdependence was fitted by rules, sequential interdependence was fitted by planning, and reciprocal interdependence was fitted by mutual adjustment (for this to hold these three types of interdependence have to be successively higher in their uncertainty).

Lawrence and Lorsch saw that firms of low rate of product change have only sequential interdependence between their functional departments (e.g., Sales and Production). This can be handled effectively by centralized planning. In contrast, firms in environments of high rate of product change have work that flows back and forth unpredictably between Sales, Production, and R&D. Thus, there is reciprocal interdependence between their functional departments. To be handled effectively, this requires individuals and project teams that liaise between the functional departments. Therefore, a medium level of integration fits a medium level of interdependence (i.e., sequential), while a high level of integration fits a high level of interdependence (i.e., reciprocal). Hence, integration primarily needs to fit interdependence.

In a diversified corporation, its divisions have no direct task connections, that is to say, there is only pooled interdependency, the lowest level of interdependence between the divisions. Thus, they can be adequately coordinated by a low-level integration, such as by having rules about the financial reporting of the divisions to the corporate head office. It does not matter whether the divisions are lowly differentiated from each other, or highly differentiated, because there is no direct task connection between them and so little integration needed. Hence, their integration is not causally related to their differentiation – DnI does not hold.

Configurationism or Cartesianism?

Some early research postulated that each level of a contingency variable (e.g., size) is fitted by a different level of a structural variable (e.g., specialization), so that fit is a continuous line (Child, 1975). This has been called the Cartesian view. In contrast, some researchers hold that there are only few fits, which they call configurations or gestalts. These are held to be widely separated, so that an organization rarely moves from one fit to another, other than by a quantum jump, and may fall back to the first fit. Thus, such configurationism implies that organizations take only few values on the contingency and structural variables (e.g., only simple structures that are of small size and low formalization, or machine bureaucracies that are large and high on formalization), whereas empirical research shows that they take many values, supporting Cartesianism. Configurationism also implies that organizations seldom change their values on the contingency and structural variables, whereas empirical research shows that they frequently do so. Furthermore, configurationism implies that when organizations do change it is through large changes in the contingency and structural variables, whereas empirical research shows that they typically make only incremental changes. Cartesianism holds that, because fits form a continuous line, an organization can move from one fit to an adjacent fit, and in that way make frequent changes and change considerably over time through an incremental process. This is a more plausible and empirically backed view than Configurationism (Donaldson, 2001). However, some configurationists (Greenwood and Hinings, 1993) are referring to the cognitive configurations in the minds of people and these can be few and discrete, so the idea of cognitive configurations is sound.

Structures Fitting Contingencies or Other Structures?

The idea that the fit of structure to a contingency affects performance was extended to the idea that structural variables needed to fit *other structural variables* to attain high performance.

This opens the door to dispensing with there being any fit to contingency factors, which means managers need not be restricted in their choices of structure to those that fit some contingency factor.

Equifinality

Equifinality here means many ways of achieving the same end. Applied in the mainstream contingency literature, it means that there is not just one structure that fits the circumstances of an organization, so that multiple structures or combinations of structural variables fit the organization, allowing its managers a wide realm of choice.

Contingency Imperative or Strategic Choice?

The picture of organizational change in the pioneering work is that changes in contingencies cause changes in structure, so the organization moves from one fit to another. This seems an almost automatic process in which managerial choices of structure are determined by a contingency imperative. Child (1972) challenged this view and asserted strategic choice. He argues that various factors intervene to loosen the connection between contingency change and structural change, so that managers exercise choice. Performance lost from misfit may be compensated for by performance from other sources, so that performance maintains an acceptable level and change is avoided. Misfit may be regained through adjusting contingency to structure, avoiding having to adopt a new structure. Managerial perceptions, beliefs, and interests may mediate in the change process. Also, if fit is really just to other structural variables, this also avoids having to bow to contingency dictates. And if structural combinations are equifinal then this also avoids having to adopt a particular structure because of contingencies.

This strategic choice (Child, 1972) revision of structural contingency theory has proved popular. However, Donaldson (2001) has offered a rebuttal of many of the arguments for strategic choice. In its place he has offered structural adaptation to regain fit (Donaldson, 2001) which holds that contingency change causes structural change but after a delay until performance drops below the acceptable level, thereby retaining one of Child's mediating processes.

Current and Emerging Directions in Theory and Research

In the early 1980s, there were suggestions that the topic of organizational design was matured out. And there has been the claim that research on structural contingency theory has stopped from the early 1980s. A critique of structural contingency theory was published around that time that was quite influential (Schoonhoven, 1981), though not clearly amounting to a refutation of structural contingency theory. However, subsequent research into structural contingency theory has been conducted and continues to appear in the published literature (e.g., Hill et al., 1992; Jennings and Seaman, 1994; Keller, 1994; for a fuller review see Donaldson, 2001). This is in part because organization design remains a topic of practical importance in business schools and structural contingency theory continues to be the core of the way it is studied (Jensen et al., 2010; Burton and Obel, 2011). As lately as 2010, scholars have called for renewed efforts into organizational design research involving structural contingency theory (in synthesis with other contemporary organizational theories such as institutional theory) (Greenwood and Miller, 2010). There are also moves to apply structural contingency theory out to other domains, such as operations management (Sousa and Voss, 2008), and to topics such as outsourced work (Hsiao-Hui et al., 2011) and supply chains (Wong et al., 2002).

Isoperformance and Heteroperformance

The core of structural contingency theory is that fit of structure to contingency leads to higher performance than does misfit between them. Early work provided some empirical evidence that firms in misfit had lower performance than firms in fit, with misfit occurring through structure being either below (underfit) or above (overfit) the fitting level (Woodward, 1965). Subsequent work held that the farther away from fit, that is, the greater the misfit, the lower performance would be as a consequence. Moreover, each fit produces the same level of high performance as any other fit, a view known as isoperformance (iso meaning equal).

For contingencies that are internal to the organization, however, the problem arises as to why its managers should increase its level of the contingency variable such as size, which is clearly costly, if there is no performance gain. An attempt to resolve this problem has led to the creation of heteroperformance theory ('hetero' because performance varies) (Donaldson, 2001). This states that the fit to a higher level of the contingency variable (e.g., size) produces higher performance than the fit to the next lower level of the contingency variable. For example, an increase in size means there are more employees in a firm to produce output, so that, if it adopts the level of (say) specialization that fits that size, that fit will produce more performance than will the fit of specialization to the lower level of size. Specialization fitting size produces performance, but also increasing size increases performance. Hence, there is an incentive for managers to move their organization from it being in fit to a lower level of size to it being in fit to a higher level of size. By moving incrementally from one fit to the next, the organization can grow over time from being small to large. This may be interpreted as an explanation as to why there is such a range in size of organizations. The same argument applies for other internal contingencies.

Isoperformance holds for external contingencies, however. Where, for example, the environment of an organization becomes more uncertain, that raises the level of that contingency variable without the managers of that organization doing anything to increase the uncertainty of their organization's environment. The managers require no incentive from some increased performance due to higher levels of the contingency variable. Thus, even where fits all produce the same performance level (i.e., isoperformance) the external contingency can take various values across organizations.

These considerations lead to a modification in structural contingency theory to say that heteroperformance holds for internal contingencies (e.g., size) whereas isoperformance still

holds for external contingencies (e.g., environmental uncertainty). Thus, the core fit-performance model of structural contingency theory has become elaborated. This remains at this time a theoretical development and testing its empirical validity is a task for future research.

Asymmetric Effects on Performance of Overfit and Underfit

A further elaboration of structural contingency theory is the suggestion that the effects of misfit on performance are asymmetric. Traditionally, in structural contingency theory, the effect of misfits on performance are presumed to be symmetric, in that overfit is seen as producing the same performance loss as underfit (Woodward, 1965). However, it has been argued that overfit produces less performance loss than underfit. An organization in overfit has too high a structural level, and therefore has an unnecessarily complex and costly structure. This means the organization attains its objectives, but with excessive costs, which adversely affects its performance, but not seriously. In contrast, an organization in underfit has too low a structural level to fit the contingency and therefore cannot attain its objectives, which is more serious for performance. This theoretical idea needs more empirical research in the future to ascertain its validity and the degree of difference between overfit and underfit in their effects on performance.

Matrix Structures

Matrix structures were seen as a beneficial innovation in the 1970s but became a less popular idea. However, twenty-first century research has found that large corporations are adding matrices to deal with the increasing complexity they face. Scholars had said they were needed for organizations with dual focus (e.g., function and products). Wolf and Egelhoff (2002) defined the fits of matrix structures to various contingencies, based on the information-processing needs posed by the contingencies. Scholars had argued that in multinational corporations, matrix structures would be the fit where product and area diversification were both high, but empirical research found little support. More recently, it has been shown that matrix structures of several types all fit the combination of high local responsiveness and high global integration. Adding foreign product diversification back in, creates a model of three contingencies whose combinations are each fitted by one of nine different structures (Qiu and Donaldson, 2010). This model requires further empirical testing.

Systems Fits?

Structural contingency theory holds that there are bivariate fits of a structural variable to a contingency variable that affects performance. In contrast, it has been asserted that multiple fits between numerous structural and contingency variables lead to the existence of systems fits. These are said to have holistic or emergent types of properties such that the effect on performance of a systems fit is different from that would obtain if the bivariate fits were just summed together. While this idea has gained some currency, however, it is noteworthy that in the model proposing systems fits the overall effect on performance is really just the sum of the effects of the bivariate fits (see Donaldson, 2001).

Selection?

On occasion, the word selection has been used to describe the fact that structures are brought into fit. However, given the influence of organizational (or population) ecology theory in organizational theory, selection has connotations of natural selection through death and birth processes, whereas the idea of 'selection' here is that managers choose structures. The insightful point that accompanies this language is that managers may be constrained in the range of structures they can choose because of constraints on them, e.g., middle managers' limited authority in the face of head office instructions. The term managerial choice (Donaldson, 2001) might be preferable to selection in conveying this idea.

New Contingency Variables?

Above we discussed three main contingencies: uncertainty, size, and strategy. However, structural contingency theory is amenable to the identification of more contingency factors. Knowledge has more recently become of interest to organizational theories and structural variables about organizational knowledge have been shown to have fits with contingencies (Birkinshaw et al., 2002). The development of new contingency-structural fits is an open agenda for structural contingency theory in the future.

Links to Databases and Software

Computer software is available that gives the structure needed for an organization to fit its contingencies. The analyst enters the levels of the contingencies of an organization and the software gives the optimal structure. It is called 'OrgCon.' It draws on a comprehensive set of contingencies and corresponding structural factors (Burton and Obel, 2004).

Abstract

Structural equation modeling refers to a broad statistical framework that involves the specification of a substantive or theoretical model, potentially involving latent or unobserved variables, and the testing of the model with respect to observed data. This article presents the general model, discusses model identification, provides an overview of estimators for structural equation models, outlines testing both the overall fit of a hypothesized model and specific parameters, and notes a couple of notable developments with structural equation models.

Structural equation modeling refers to a broad statistical framework that involves the specification of a substantive or theoretical model and the testing of the model with respect to observed data. Structural equation models, with roots in psychometrics, econometrics, sociological methods, and earlier work in genetics, allow for the presence of unobserved, or latent, variables and the specification of systems of equations (Bollen, 1989). The inclusion of latent variables allows researchers to explicitly address measurement error in observed variables, which is an important feature of the structural equation modeling framework. This article provides an overview of structural equation models including a consideration of both the traditional general model as well as an overview of important recent developments in structural equation modeling.

The article is organized as follows. The first section presents the traditional general structural equation model. The second section discusses model identification, an issue that is typically more prominent in structural equation models than in many other statistical models. The third section provides a brief overview of commonly used estimators for structural equation models, including estimators for categorical data. One particularly useful feature of structural equation models is the ability to test or assess the overall fit of the models. The fourth section presents a number of different approaches to testing structural equation models. Finally, the fifth section provides a brief note of three important extensions or developments of structural equation modeling.

The General Model

The general structural equation model as outlined by Jöreskog (1973) consists of two parts: (1) the latent variable model links latent variables to each other via systems of simultaneous equations and (2) the measurement model links latent variables to observed variables via a restricted (confirmatory) factor model. Using a slightly modified version of Jöreskog's (1977) LISREL notation, the latent variable model is

$$\boldsymbol{\eta}_i = \boldsymbol{\alpha}_\eta + \mathbf{B}\boldsymbol{\eta}_i + \boldsymbol{\Gamma}\boldsymbol{\xi}_i + \boldsymbol{\zeta}_i \qquad [1]$$

where i indexes observations, $\boldsymbol{\eta}$ is a vector of endogenous latent variables, $\boldsymbol{\xi}$ is a vector of exogenous latent variables, and $\boldsymbol{\zeta}$ is a vector of disturbance terms for each of the endogenous latent variables. The parameters in the model include a vector of intercepts ($\boldsymbol{\alpha}_\eta$), a matrix of regression coefficients that gives the effects of the latent endogenous variables on each other ($\mathbf{B}$), and the effects of the latent exogenous variables on the latent endogenous variables ($\boldsymbol{\Gamma}$). The matrix $\boldsymbol{\Phi}$ contains the variances and covariances among the exogenous latent variables and the matrix $\boldsymbol{\Psi}$ contains the variances and covariances among the disturbances for the latent endogenous variable.

The measurement model links observed variables to endogenous and exogenous latent variables. The equations for the measurement model are

$$\mathbf{y}_i = \boldsymbol{\alpha}_\mathrm{y} + \boldsymbol{\Lambda}_\mathrm{y}\boldsymbol{\eta}_i + \boldsymbol{\varepsilon}_i \qquad [2]$$

and

$$\mathbf{x}_i = \boldsymbol{\alpha}_\mathrm{x} + \boldsymbol{\Lambda}_\mathrm{x}\boldsymbol{\xi}_i + \boldsymbol{\delta}_i \qquad [3]$$

where $\mathbf{y}$ is a vector of observed indicators of the ηs (latent endogenous variables), $\mathbf{x}$ is a vector of observed indicators of the ξs (latent exogenous variables), and $\boldsymbol{\varepsilon}$ and $\boldsymbol{\delta}$ are, respectively, vectors of disturbances for the observed indicators of the latent variables. The matrix of coefficients, often referred to as factor loadings, $\boldsymbol{\Lambda}_\mathrm{y}$ gives the effects of the ηs on the ys and similarly $\boldsymbol{\Lambda}_\mathrm{x}$ gives the effects of the ξs on the xs. The measurement models also include vectors of intercepts $\boldsymbol{\alpha}_\mathrm{y}$ and $\boldsymbol{\alpha}_\mathrm{x}$. Finally, the matrix $\boldsymbol{\Theta}_\varepsilon$ contains the variances and covariances among the $\boldsymbol{\varepsilon}$ disturbances and the matrix $\boldsymbol{\Theta}_\delta$ contains the variances and covariances among the $\boldsymbol{\delta}$ disturbances.

There are a number of assumptions that typically underlie the latent variable model and measurement model. First, it is assumed that expected values for all the disturbances equal 0, i.e., $E[\boldsymbol{\zeta}_i] = E[\boldsymbol{\varepsilon}_i] = E[\boldsymbol{\delta}_i] = 0$. Second, it is assumed that the exogenous latent variables are uncorrelated with the disturbances in the latent variable model and that the endogenous and exogenous latent variables are uncorrelated with the disturbances in the measurement model, i.e., $\mathrm{Cov}[\boldsymbol{\xi}_i, \boldsymbol{\zeta}_i] = \mathrm{Cov}[\boldsymbol{\eta}_i, \boldsymbol{\varepsilon}_i] = \mathrm{Cov}[\boldsymbol{\xi}_i, \boldsymbol{\delta}_i] = 0$. Finally, it is generally assumed that the disturbances across eqns [1]–[3] are uncorrelated with each other, but this assumption is less essential than the previous two.

Structural equation modeling is a methodology designed primarily to test substantive theories. As such, a theory should be sufficiently developed to suggest that certain latent variables do not affect other latent variables, certain observed variables do not load on certain latent variables, and certain disturbances and measurement errors do not covary. This implies that some

of the elements of $\mathbf{B}$, $\mathbf{\Gamma}$, $\mathbf{\Lambda}_y$, $\mathbf{\Lambda}_x$, $\mathbf{\Phi}$, $\mathbf{\Psi}$, $\mathbf{\Theta}_\varepsilon$, and $\mathbf{\Theta}_\delta$ are fixed to zero by hypothesis. The remaining parameters are free to be estimated. The pattern of fixed and free parameters implies a specific structure for the moment matrices of the observed variables. In this way, structural equation modeling can be seen as a special case of a more general covariance structure model defined as $\boldsymbol{\mu} = \boldsymbol{\mu}(\boldsymbol{\theta})$ and $\mathbf{\Sigma} = \mathbf{\Sigma}(\boldsymbol{\theta})$, where $\boldsymbol{\mu}$ and $\mathbf{\Sigma}$ are, respectively, the population mean vector and covariance matrix and $\boldsymbol{\mu}(\boldsymbol{\theta})$ and $\mathbf{\Sigma}(\boldsymbol{\theta})$, referred to as the 'implied moment matrices,' are matrix valued functions of the parameter vector $\boldsymbol{\theta}$ containing all the parameters of the hypothesized model.

Identification

A prerequisite for the estimation of the parameters of the model is to establish whether the model is identified, i.e., whether it is possible to find unique values for each of the parameters in the model contained in $\boldsymbol{\theta}$. The elements in $\boldsymbol{\theta}$ are identified if they can be expressed uniquely in terms of the elements of the population moment matrices $\boldsymbol{\mu}$ and $\mathbf{\Sigma}$. If all elements in $\boldsymbol{\theta}$ are identified then the model is identified. If there are just enough elements in the population moment matrices to identify the parameters, then the model is said to be 'just identified.' If there are more than enough elements, then the model is said to be 'overidentified.' The distinction is important in that global tests of model fit (discussed below) are available only for overidentified models. Identification concerns the existence of unique values for the parameters and thus should be established prior to estimation (although, as noted below, one of the popular means of establishing identification occurs in the process of estimation).

There are three approaches to establishing the identification of a structural equation model in the general model framework. The first approach is to determine whether the model conforms with one of the known rules for identified models (see Bollen (1989) for a discussion of a number of well-known rules of identification). The second approach, which is perhaps the most frequently used in practice, is to rely on empirical identification tests that are typically incorporated into the software used to estimate structural equation models (SEMs). Empirical tests of identification, however, assess local rather than global identification (i.e., whether unique values for the parameters exist in a local neighborhood rather than across the complete parameter space) and thus can be misleading in some cases. The third approach is to prove through algebraic means that all the parameters can be uniquely expressed in terms of the population moment matrices $\boldsymbol{\mu}$ and $\mathbf{\Sigma}$. This approach can be quite challenging with large models as the algebra becomes complex, although computer algebra systems can assist in the process (Bollen and Bauldry, 2010). Nonetheless, it is the only foolproof method of establishing identification for models that do not conform to one of the known rules of identification.

Estimation

Parameter estimation involves obtaining estimates of the free parameters of the model, subject to the constraints imposed by the fixed parameters of the model. The goal is to apply a model to the sample moment matrices $\mathbf{z}$ and $\mathbf{S}$, which are estimates of the population moment matrices $\boldsymbol{\mu}$ and $\mathbf{\Sigma}$ that are assumed to follow a hypothesized structural equation model. Estimates are obtained such that the discrepancy between the estimated moment matrices $\hat{\boldsymbol{\mu}} = \boldsymbol{\mu}(\hat{\boldsymbol{\theta}})$ and $\hat{\mathbf{\Sigma}} = \mathbf{\Sigma}(\hat{\boldsymbol{\theta}})$ and the sample moment matrices $\mathbf{z}$ and $\mathbf{S}$ are as small as possible. There are a number of estimators that have been developed for structural equation models.

Maximum Likelihood Estimators

The most frequently used estimator for structural equation models is the maximum likelihood (ML) estimator. The ML estimator has a number of desirable properties (Bollen, 1989). ML estimators are asymptotically unbiased, consistent, and asymptotically efficient. In addition, ML estimators are asymptotically normally distributed, which ensures that the ratio of the parameters to their standard errors approximates a Z distribution in large samples. ML estimators also provide an overall model fit test (for overidentified models). Finally, as described below, ML estimators can be extended relatively easily to address missing data subject to certain assumptions.

The ML estimator was originally derived under the assumption of multivariate normality. Browne (1987), however, demonstrated that ML estimators maintain their desirable asymptotic properties even with nonnormal data as long as there is no excess multivariate kurtosis. In addition, numerous simulation studies find that the ML estimator is largely robust to departures from normality in finite samples across a range of research contexts. Finally, corrections have been developed for chi-square test statistics and standard errors of parameter estimates that adjust for nonnormality when using ML estimators (Satorra and Bentler, 1994).

Model-Implied Instrumental Variable Estimators

ML estimators are sometimes referred to as full-information estimators in that they involve the simultaneous estimation of all of the parameters of a given model using information from the whole system of equations. By contrast, limited information estimators operate on single equations or subsets of equations. An important class of limited information estimators is instrumental variable estimators. In a series of papers, Bollen and colleagues developed what are now known as model-implied instrumental variable estimators for structural equation models (Bollen, 1996; Bollen and Maydeu-Oliveres, 2007; Bollen et al., forthcoming). These estimators include families of two-stage least squares (2SLS) and generalized method of moments (GMM) estimators. The instruments used in these estimators arise from the specification of the model, hence the term 'model-implied' instruments.

As limited information estimators, the model-implied instrumental variable estimators are not as asymptotically efficient as full-information estimators, but they have a number of advantages over the more commonly used ML estimators for structural equation models. First, the fact that they operate on single equations or subsets of equations helps isolate potential bias due to misspecification in other parts of the model. Second, these estimators are

asymptotically distribution free and thus do not rely on a multivariate normality assumption. Finally, simulation studies suggest that the efficiency trade-off as compared with a full-information estimator is not that large. To date, however, model-implied instrumental variable estimators have not enjoyed widespread use in empirical research using structural equation models.

Estimators for Categorical Observed Variables

Although ML estimators are robust to moderate departures from normality, it is still desirable to have estimators that explicitly account for categorical observed variables. There are broadly two classes of estimators for categorical observed variables in structural equation models. The first class is based on positing that each of the categorical observed variables has an underlying latent variable that is continuous and normally distributed (Olsson, 1979; Muthén, 1984). The correlations among these underlying latent variables, sometimes referred to as polychoric correlations, can be used in combination with a weight matrix in diagonally weighted least squares estimator (Jöreskog and Sörbom, 1993; Muthén, 1984). The second class of estimators involves extending the measurement model given in eqns [2] and [3] to be a generalized linear model in which different link functions allow for different types of variables (Skrondal and Rabe-Hesketh, 2004). ML estimation with this approach, in contrast to the model assuming multivariate normality, cannot be based on sufficient statistics and thus relies on more computationally demanding approaches that typically involve 'integrating out' the latent variables.

Complex Sampling Designs and Missing Data

In the absence of explicit information to the contrary, estimation methods such as ML assume that data are generated according to simple random sampling. Perhaps more often than not, however, structural equation models are applied to data that have been obtained through something other than simple random sampling. For example, when data are obtained through multistage sampling, the usual assumption of independent observations is violated resulting in predictable biases. Estimators for structural equation models that account for complex sampling designs have been developed and are available in most of the widely used software packages for estimating structural equation models (Muthen and Satorra, 1995).

Traditionally, statistical procedures such as structural equation modeling assume that each unit of analysis has complete data. However, for many reasons, units may be missing values on one or more of the variables under investigation. Numerous ad hoc approaches exist for handling missing data, including listwise and pairwise deletion. However, these approaches assume that the missing data are unrelated to the variables that have missing data and any other variable in the model (i.e., missing completely at random in Little and Rubin's (2002) terminology), an often untenable assumption.

There are two contemporary approaches to addressing missing data that can be used with structural equation models and rely on the less stringent assumption that the missing data is unrelated to the variable missing data conditional on the variables in the model (i.e., missing at random in Little and Rubin's (2002) terminology). The first procedure, the one most commonly used for structural equation modeling, is to use a casewise ML (or direct ML) estimator. This estimator is an extension of the standard ML estimator that allows one to maintain all the cases in the estimation of parameters (Arbuckle, 1996). The second procedure is to use multiple imputation, which involves constructing M complete data sets using an imputation model to fill in the missing data along with some random error to reflect the imputation process, estimating the structural equation model on each complete data set, and then combining the estimates using Rubin's rules (Little and Rubin, 2002).

Testing

Once the parameters of the model have been estimated, the model can be tested for global fit with the data. In addition, hypotheses concerning individual parameters can be evaluated.

Testing Global Model Fit

A feature of ML estimators is that with overidentified models one can explicitly test the hypothesis that the model fits data. The null hypothesis states that the specified model holds in the population, i.e., H_0: $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\theta})$. The corresponding alternative hypothesis is that the population covariance matrix is some other symmetric positive definite matrix. With an ML estimator, the fitting function is given by F_{ML}. The function $(N-1)$ F_{ML} has an asymptotic chi-square distribution with $\frac{1}{2}(p+q)(p+q+1)-t$ degrees of freedom where p is the number of observed indicators of $\boldsymbol{\eta}$ (ys), q is the number observed indicators of $\boldsymbol{\xi}$ (xs), and t is the number of free parameters in the model. A significant chi-square statistic indicates that $\boldsymbol{\Sigma} \neq \boldsymbol{\Sigma}(\boldsymbol{\theta})$ and thus H_0 is rejected and at least one component of the specified model is incorrect.

Similar model fit statistics are available with model-implied instrumental variable estimators. In the context of structural equation models, the well-known overidentification tests associated with instrumental variable estimators, such as Sargan's chi-squared statistic for 2SLS estimators and Hansen's J statistic for GMM estimators (Sargan, 1958; Hansen, 1982), serve as tests of model misspecification.

Testing Hypotheses regarding Individual Parameters

In addition to a global test of whether the model holds exactly in the population, one can also test hypotheses regarding the individual fixed and free parameters in the model. There are a few alternative ways to evaluate the fixed and freed elements of the model vis-à-vis overall fit.

One important method rests on the difference between the chi-square statistics comparing a given model against a less restrictive model. Recall that the initial hypothesis, say $H_{0\mathrm{R}}$, is tested against the alternative hypothesis H_{a} that $\boldsymbol{\Sigma}$ is some other symmetric positive definite matrix. Consider a second hypothesis, say $H_{0\mathrm{U}}$ that differs from $H_{0\mathrm{R}}$ in that a single parameter that was restricted to 0 in model R is now relaxed in model U. Note that the alternative hypothesis is the same

in both cases. Therefore, the change in the chi-square value between the two models can be used to test the improvement in fit due to the relaxation of the restriction. The distribution of the difference between the two chi-square tests is itself distributed as chi-square with degrees of freedom equal to the difference in degrees of freedom between the model under H_{0R} and the less restrictive model under H_{0U}. In the case of a single restriction described here, the chi-square difference test is evaluated with one degree of freedom.

Alternative Methods of Assessing Model Fit

Since the early 1980s, attention has focused on the development of alternative indices that provide relatively different perspectives on the fit of structural equation models. The development of these indices has been motivated, in part, by the known sensitivity of the chi-square statistic to large sample sizes. Other classes of indices have been motivated by a need to rethink the notion of testing exact fit in the population – an idea that is deemed by some to be unrealistic in most practical situations.

In this section, the discussion of alternative fit indices is divided into three categories: (1) measures based on comparative fit to a baseline model, (2) measures based on population errors of approximation, and (3) the Bayesian information criterion (BIC). In addition to the chi-square test statistic, each of these alternative fit indices have strengths and weaknesses, so the current recommendation for empirical research using structural equation models is to report multiple fit statistics and assess the pattern of information across the statistics regarding model fit.

Measures Based on Comparative Fit to a Baseline Model

The basic idea behind comparative fit indices is that the fit of the model is compared to the fit of some baseline model that usually specifies complete independence among the observed variables. The fit of the baseline model will usually be fairly large and thus the issue is whether one's model of interest is an improvement relative to the baseline model. The index is typically scaled to lie between 0 and 1, with 1 representing perfect fit relative to this baseline model. The sheer number of comparative fit indices precludes a detailed discussion of each one. A subset of indices that serve to illustrate the basic ideas is considered here.

The most straightforward, although rarely used, example of a comparative fit index (CFI) is the normed fit index (NFI) proposed by Bentler and Bonett (1980). This index can be written as

$$\mathrm{NFI} = \frac{T_b - T_m}{T_b}, \qquad [4]$$

where T_b is the chi-square test statistic for the model of complete independence (the so-called baseline model) and T_m is the chi-square test statistic for the target model of interest. This index, which ranges from 0 to 1, provides a measure of the extent to which the target model is an improvement over the baseline model.

The NFI assumes a true null hypothesis and therefore a central chi-square distribution of the test statistic. However, an argument could be made that the null hypothesis is never exactly true and that the distribution of the test statistic can be better approximated by a noncentral chi-squared with noncentrality parameter λ. An estimate of the noncentrality parameter can be obtained as the difference between the statistic and its associated degrees of freedom. Thus, for models that are not extremely misspecified, an index developed by McDonald and Marsh (1990) and referred to as the relative noncentrality index (RNI) can be defined as

$$\mathrm{RNI} = \frac{(T_b - \mathrm{df}_b) - (T_m - \mathrm{df}_m)}{T_b - \mathrm{df}_b}, \qquad [5]$$

where df_b and df_m are the degrees of freedom, respectively, for the baseline and target model. The RNI can lie outside the 0–1 range. Bentler (1990) adjusted the RNI so that it would lie in the range of 0–1. This adjusted version is referred to as the CFI and is often preferred in practice, although it can obscure overfit as indicated by values of the RNI that are greater than 1.

Measures Based on Errors of Approximation

It was noted earlier that the chi-square test assesses an exact null hypothesis that the model fits perfectly in the population. In reality, it is fairly unlikely that the model will fit the data perfectly. In addition, as the sample size grows larger, the power of the chi-square test increases and thus the ability to detect potentially trivial model misspecifications arises. An alternative approach is to assess whether the model fits approximately well in the population.

Based on the work of Steiger and Lind (1980), it is possible to assess the approximate fit of a model in the population. The method of Steiger and Lind (1980) utilizes the root mean square error of approximation (RMSEA). The RMSEA is given by

$$\mathrm{RMSEA} = \sqrt{\frac{T_m - \mathrm{df}_m}{\mathrm{df}_m(N-1)}}. \qquad (6)$$

In utilizing the RMSEA for assessing approximate fit, a formal hypothesis testing framework is employed. Typically an RMSEA value ≤ 0.05 is considered a 'close fit.' This value serves to define a formal null hypothesis of close fit. In addition, a 90% confidence interval around the RMSEA can be formed, enabling an assessment of the precision of the estimate (Steiger and Lind, 1980). Practical guidelines suggest that values of the RMSEA between 0.05 and 0.08 are indicative of fair fit, while values between 0.08 and 0.10 are indicative of mediocre fit. Simulation studies, however, indicate that these guidelines do not perform well in small samples.

Bayesian Information Criterion

The BIC is a well-known general approach to model selection that favors more parsimonious models over more complex models (i.e., it adds a penalty based on the number of parameters being estimated in the model) (Schwarz, 1978; Raftery, 1995). One form for calculating the BIC is given by

$$\mathrm{BIC} = T_m - \mathrm{df}_m \ln(N), \qquad (7)$$

where T_m is the chi-square statistic for the hypothesized model. In this form, a BIC greater than 0 favors the saturated model (i.e., the model that allows all observed variables to be intercorrelated with no assumed model structure), while a BIC less

than 0 favors the hypothesized model. Furthermore, the BIC can be used to assess two competing models. Following Jeffrey-Raftery's (1995) guidelines, if the difference in BICs between the two models is 0–2, this constitutes 'weak' evidence in favor of the model with the smaller BIC; a difference in BICs between 2 and 6 constitutes 'positive' evidence; a difference in BICs between 6 and 10 constitutes 'strong' evidence; and a difference in BICs greater than 10 constitutes 'very strong' evidence in favor of the model with smaller BIC.

Developments and Extensions

Structural equation modeling continues to be a dynamic area of research with numerous areas of development and extensions to other types of analytic strategies. Space constraints make it impossible to highlight all the modern developments in structural equation modeling. This section focuses on two increasingly popular classes of structural equation models, growth curve models and latent class models, and the connection between graphical models and SEMs.

Growth Curve Models

Social science researchers increasingly have access to and rely on longitudinal data for analyzing processes that unfold over time and interindividual differences in these processes. Traditionally, the specification of growth models falls within the class of random effects models or multilevel linear models in which multiple observations over time are nested within individuals (Raudenbush and Bryk, 2001; Wooldridge, 2002). Growth curve models have also been incorporated into the structural equation modeling framework by treating the growth parameters as latent variables (Bollen and Curran, 2006). The advantages of the structural equation modeling framework for growth curve modeling lies in its flexibility in specifying and testing models of substantive interest.

Latent Class Models

The defining characteristic of latent class models is the inclusion of categorical latent variables as opposed to the continuous latent variables assumed in the traditional structural equation modeling framework. Latent class models are typically used when a researcher suspects that distinct subgroups or categories of individuals exist in a population. These models have an affinity with the person-oriented approach advocated by Bergman and Magnusson (1997). Recent interest in latent class models has focused on their extension to longitudinal data and the modeling of different growth trajectories (Collins and Lanza, 2010).

Graphical Models and Structural Equation Models

Judea Pearl's work using directed acyclic graphs to represent causal models has been widely influential in statistics and is gaining traction in the social sciences (Pearl, 2000, 2010). There is a natural affinity between Pearl's graphical models and SEMs given their shared focus on causal modeling and figure-oriented notation, although there remain some important differences. For instance, Pearl's framework is non-parametric, whereas SEMs traditionally rest on a linearity assumption (although this can be relaxed to some extent (Bollen and Pearl, 2013)). On the other hand, the SEM framework pays more attention to latent variables and measurement error than has so far been the case with graphical models.

Structural Equivalence: Meaning and Measures

Abstract

In social network analysis, two nodes are considered structurally equivalent if they have the same neighborhoods – that is, they are connected to the same others. Initially introduced as a convenience for creating reduced models of networks, it was soon seen as a way to formalize the concept of relational role or position. To the extent that characteristics of nodes are shaped by their social environments, we expect structurally equivalent nodes to develop similar characteristics. Structural equivalence has been used to explain similarities in beliefs and attitudes, the adoption of innovation, the evolution of interfirm networks, political affiliation, the structure of trade among nations, and the effects of technology change.

In social network analysis, two nodes are structurally equivalent to the extent that they have ties to the same third-parties. An example is shown in Figure 1, where nodes B and D are structurally equivalent. Both nodes have an outgoing tie to E, and both have incoming ties from A and C. Two key intuitions underlie the concept. One is the notion of a graph-theoretic niche – i.e., the idea of two nodes sharing the same social environment. The other is the notion of indistinguishableness, meaning that structurally equivalent nodes are structurally identical and indeed would be indistinguishable if not for their labels. Both of these ideas lead to a generic expectation that structurally equivalent nodes will tend to be similar in other, nonstructural, ways as well. For example, to the extent that a node's function, outcomes, behavior, attitudes, etc., are the result of its environment, two nodes with similar environments should develop other similarities as well. Likewise, to the extent that there are consequences to occupying certain structural positions in a network, structurally equivalent nodes should be more likely to have similar outcomes than nonequivalent nodes.

Formal Definition

The most common definition of structural equivalence is based on the same-neighborhood or social niche idea. Given an undirected graph G(V,E), a pair of vertices u and v are structurally equivalent if $N(u) = N(v)$, where $N(x)$ is the set of vertices adjacent to x. In other words, u and v are connected to the same vertices. For directed graphs, we require that $N^i(u) = N^i(v)$ and $N^o(u) = N^o(v)$, meaning that u and v have incoming arcs from the same vertices and outgoing arcs to the same vertices.

Unfortunately, this definition does not quite satisfy the indistinguishableness criterion. For example, when G is undirected and nonreflexive (i.e., no ties from a vertex to itself) if u and v are tied, it is not possible for u and v to be structurally equivalent, even though it is obvious that they are indistinguishable (see vertices A and C in Figure 1). The reason is that u's tie to v requires v to have a tie to v as well, in order to satisfy the equality of neighborhoods condition, but this is impossible if G is nonreflexive. We could patch the definition by requiring only that $N(u) - \{v\} = N(v) - \{u\}$, but this would fail if G was directed with an arc from u to v, as it would find u and v equivalent when clearly they are not (see Figure 2). A variety of other possibilities of this type fail in one circumstance or another.

A better definition is provided by Everett and Borgatti (1994), which they refer to as weak structural equivalence. In their definition, $u \equiv v$ (that is, are equivalent) if there exists an automorphism π of G of the form $\pi = (u,v)$, meaning that u and v are mapped to each other and all other vertices are mapped to themselves. With this definition, A and C in Figure 2 would not be equivalent, but would be if there were a reciprocating arc from C back to A. The Everett and Borgatti definition actually yields a lattice of equivalence relations in which the maximal element is the equivalence in which *all* vertices that can be mapped to each other are placed in the same class.

The lattice of structural equivalences is a sublattice of the lattice of regular equivalences (Everett and Borgatti, 1994). An equivalence is regular if $u \equiv v$ implies that $C(N^i(u)) = C(N^i(v))$ and $C(N^o(u)) = C(N^o(v))$, where $C(w)$ is the equivalence class of w and $C(N(w))$ is the set of equivalence classes observed in the (in- or out-) neighborhood of w. The frequency of occurrence of each class is ignored.

Figure 1 Directed graph.

Figure 2 Vertices A and C are not structurally equivalent.

Another way to think about structural equivalences is in terms of blockmodels. Blockmodeling refers to the practice of reordering and partitioning the rows and columns of an adjacency matrix so that the rows and columns of all vertices in an equivalence class are placed next to each other and are visually separated from the vertices in other equivalence classes (see Figure 3). This creates matrix blocks consisting of all dyads (u,v) whose members are involved in the same two equivalence classes.

A distinctive property of structural equivalence is that all matrix blocks consist of either all 1s or all 0s. As a result, there is no loss of information in representing the network by a reduced matrix – the blockmodel – whose rows and columns correspond to the classes of the structural equivalence (see Figure 4).

Blockmodels provide a concise way to describe both empirical and theoretical social structures. For example, the structure shown in Figure 5 is a clique structure, in which ties occur only within class, and Figure 6 is a status hierarchy, in which vertices prefer not to have ties with those below them.

The blockmodel is the adjacency matrix of the image graph of a graph homomorphism induced by the structural equivalence. That is, given a graph G and a structural equivalence S, we construct an image graph H whose vertices are the equivalence classes of S. An edge occurs in H if and only if any member of one class has a tie in G to any member of the other class. Of course, in the case of structural equivalence, if any member of one class has a tie to a member of another class, then all members of the first class have ties to all members of the second one. Hence, there is no loss of information in viewing the image graph. An example of an image graph is shown in Figure 7.

A property of the maximal structural equivalence is that the image graph contains no structurally equivalent vertices. Therefore, we cannot apply structural equivalence iteratively to obtain increasingly abstract representations of a network. Relatedly, it can be shown that, for an adjacency matrix A and a structural equivalence represented by a matrix E where $e_{ij} = 1$ if the vertices corresponding to i and j are equivalent, the Boolean product AE is equal to EA.

Methods

The earliest popular method for finding structurally equivalent nodes in empirical graphs was CONCOR (Breiger et al., 1975). Given the adjacency matrix for an undirected graph, what CONCOR does is correlate the rows of the matrix (ignoring the values along the main diagonal) to produce an initial correlation matrix C(0), then correlate the rows of the correlation matrix, producing C(1), and repeat this process k times until the cells of C(k) are all +1s or −1s. At this point, the vertices can be partitioned into two sets, with all +1s for cells within set and all −1s in cells between sets. The algorithm appears to converge in all cases where correlations are calculable (i.e., each row has positive variance), although this property has not been proved mathematically.

To obtain solutions with more than two equivalence classes, it suffices to apply the algorithm to the subgraph(s) defined by the members of one (or both) initial sets. This process can be applied iteratively until a partition with the desired number of classes is obtained. The final partition can then be used to block the adjacency matrix and construct a reduced image matrix or blockmodel.

The problem of deciding which sets to further bifurcate and which to leave alone is typically handled by using a measure of clustering adequacy. In particular, Panning (1982) recommends an eta coefficient, which is equivalent to the multiple R obtained by regressing the original adjacency matrix on a series

of dummy matrices $X^{(m)}$ where $X^{(m)}(i,j) = 1$ if the (i,j) cell is a member of the mth matrix block. This effectively constitutes an analysis of variance that measures the extent to which the variance in block densities exceeds the mean within-block variances.

An alternative to CONCOR is to submit the initial correlation matrix C(0) to any clustering algorithm. Burt (1976) argued for using the Euclidean distance between rows instead of Pearson correlation, and then applying Johnson's (1967) hierarchical clustering. Euclidean distance allows differences in means and standard deviations of rows to affect the estimate of structural equivalence, whereas correlation ignores such differences (Cronbach and Gleser, 1953). If rows are standardized to have mean 0 and standard deviation 1, the square of the Euclidean distance between two rows equals $2n(1 - r)$, where n is the number of entries in each row and r is the correlation between them.

A completely different approach is to use combinatorial optimization algorithms such as simulated annealing or tabu search (Glover, 1989) to find partitions that minimize errors (an error being a 0 in a 1-block and 1 in a 0-block). This is the approach taken by Batagelj et al. (1992).

Once a partition of nodes into (approximately) structurally equivalent nodes is obtained, it is typically used as a categorical factor in predicting node-level outcomes. For example, the dependent variable could be attitude toward a political candidate measured on a 5-point scale where +2 indicates complete support and −2 indicates complete opposition. A significant relationship between the structural equivalence partition and attitude would suggest that the attitude is, at least in part, determined by position in the network.

An alternative approach is to use the initial correlation (or distance) matrix directly rather than first finding discrete clusters of equivalent nodes and using cluster membership as a variable. In this alternative approach, the correlation between two nodes gives the degree of equivalence between them, and this is used to predict the degree of similarity in their behavior, attitudes, or other outcomes. Besides taking advantage of the continuous degrees of equivalence, this approach has the benefit of being less 'massaged' than the cluster membership variable. Clustering algorithms are numerous and can give widely different answers, leaving open the question of whether the relationship discovered between structural equivalence and an outcome variable would still be found if a different clustering algorithm had been used.

For directed graphs, we correlate not only the rows of the adjacency matrix but the columns as well. This is done by appending the $n - 1$ column entries to the $n - 1$ row entries to obtain vectors of length $2(n - 1)$ for each vertex. It is these vectors that are then correlated with each other. The same approach is used to handle multiple relations. For instance, if both friendship and advice ties were measured for a set of nodes, we would build vectors consisting of the $n - 1$ row entries in the friendship adjacency matrix, the $n - 1$ column entries in the same matrix, the $n - 1$ row entries in the advice matrix, and the $n - 1$ column entries in this matrix, creating a vector of length $4(n - 1)$. When the edges of any of the graphs are weighted, it is advisable to standardize the values in all matrices so that each of them has mean 0 and standard deviation 1. Otherwise, the social relations with the largest edge weights would dominate the measure of equivalence.

History and Significance of the Concept

The term structural equivalence was introduced and formally defined by Lorrain and White (1971) in an article about role structures. Although the title of the piece includes the term structural equivalence, the concept played a minor role in the article. Their interest was in examining compositions of social relations. For example, given the relations 'parent of' (P) and 'spouse of' (S), we can compose the PS relation, which is the 'parent of the spouse of' relation, otherwise known as the in-laws. Similarly, $P^{-1}P$ is the 'child of the parent of' relation, which we know as the sibling relation. A more complex compound relation is $P^{-1}P^{-1}PP$, which is cousin. Some of these compositions are identical to others, a condition that can be expressed as an equation. For example, if it were true that friends of friends are friends, we would find that FF = F. Lorrain and White noted that they could also declare equalities like this by fiat, either as an expression of a cultural concept (e.g., brother of spouse = spouse of sister = brother-in-law), or because empirically friends of friends were, often enough, friends. Making these kinds of identifications could radically simplify the system of compositions generated by a set of starter relations (such as P and S), and simplification or 'reduction' was the goal of their analysis.

Lorrain and White realized that if relations could be found or declared equivalent, so could nodes, and this would serve the same purpose of creating a simplified abstract model of a complex observed set of concrete relationships among a set of nodes. For example, if, in **Figure 1**, we are able to equate A and C, and also B and D, we can describe the network in more abstract terms, as shown in **Figure 7**, as a system in which there are terminal nodes (E), intermediaries (B and D), and sources (A and C).

Structural equivalence was initially seen as a way to formalize a relational view of social roles. Theorists like Nadel (1957) viewed societies as a system of positions or roles such that individuals occupying these positions had characteristic relations with other persons in their capacity as incumbents of their own positions. In support of this view, Walker et al. (1997) showed that organizations tend to remain structurally equivalent over time, even as they formed and dissolved ties with third-parties.

Over time, however, there was dissatisfaction with structural equivalence as an embodiment of the social role concept (Sailer, 1978; Borgatti and Everett, 1992). It was noticed that while structural equivalence correctly identifies a mother and father as both playing the parent role to their children (and grandparents to their children's children, and so on), it does not identify two mothers of different children as playing the same role because, by definition, structural equivalence demands having the same type of tie with the *same* others. Eventually, the notion of regular equivalence, first defined in print by White and Reitz (1983), came to supplant structural equivalence as a structural definition of social role.

However, structural equivalence remains an important concept as an explanatory factor in the study of social

homogeneity (Erickson, 1988). As noted above, a number of mechanisms can be proposed for why structurally equivalent nodes might be similar in behavior, attitudes, knowledge, or, in the case of collective actors such as firms, internal structures. One mechanism is third-party contagion since structurally equivalent nodes have third-parties in common. Another mechanism is based on the indistinguishableness property of structural equivalence. For any structural process (i.e., one whose course depends entirely on the structure of the network and not the characteristics of the nodes), we expect structurally equivalent nodes to have similar outcomes. For example, if the process involves random walks through the network, the number of times something lands on each node should have the same expected value for structurally equivalent nodes.

Another mechanism is suggested by social comparison theory (Festinger, 1954), which argues that individuals are especially influenced by those they see as similar. Hence, assuming structurally equivalent nodes are aware of their equivalence and are aware of each other's attitudes, they should tend to imitate each other. This perspective was used by Burt (1987) to explain why physicians were more likely to adopt a new drug which their structural equivalents adopted.

Since then, there has been considerable debate in the sociological literature about whether structural equivalence or dyadic cohesion (e.g., being adjacent) is the better predictor of similarity on outcomes like behavior and attitude (Mizruchi, 1993). At a theoretical level, it makes sense to distinguish between the similar opportunities and constraints afforded by a common structural position and the diffusion of something flowing from node to adjacent node. Unfortunately, structural equivalence was not the best way to examine this distinction empirically because structural equivalence embodies both poles of the debate (Borgatti and Everett, 1992).

Empirical Applications

Measures of structural equivalence have been used in a number of empirical studies in the social sciences, particularly in sociology and organizational science. The list of phenomena that have been studied by taking a structural equivalence approach includes the evolution of interfirm networks (Madhavan et al., 1998; Stuart, 1998; Walker et al., 1997), the diffusion of innovations (Burt, 1987), the effects of technological change (Barley, 1990), patterns of political affiliation (Padgett and Ansell, 1993), and attitude and belief similarity among individuals (Burkhardt, 1994; Erickson, 1988; Galaskiewicz and Burt, 1991). Below, we review four highly cited empirical studies that have used measures of structural equivalence as a major component of their methodology. This review is not meant to be an exhaustive review of empirical studies of structural equivalence, but rather to provide a summary overview of how structural equivalence has been applied empirically. We begin with studies at a macrolevel of analysis and then progress to studies at a more microlevel.

Structural equivalence has been widely used in studies of interorganizational relationships in the management field. One example of such a study is that of Walker et al. (1997), who used structural equivalence as a measure of social capital in their study of network formation in the biotechnology industry. Walker et al. gathered data on the partnership ties of biotech start-up firms between the years 1984 and 1988. They then ran CONCOR analyses, coupled with the CALCOPT algorithm, in order to group firms into structurally equivalent blocks. These researchers sought to determine whether the start-up firms would have a tendency to form new ties within their structural blocks in order to capitalize on the social capital benefits of network closure (Coleman, 1990), or form ties outside of their groupings in order to capitalize on network brokerage opportunities (Burt, 1992). This study found that, over time, the biotech start-ups tended to form new ties with partners with whom they were structurally equivalent, thus providing evidence that the firms in this industry tend to reproduce network structure. Walker et al. also examined structural equivalence among the start-ups at the dyadic level and found that if two firms were structurally equivalent at the beginning of the time period of their study, then those two firms were likely to remain structurally equivalent over time. Conversely, start-ups that were not structurally equivalent where highly likely to remain so, thus providing evidence for the relative rigidity of this particular network.

A second example of a study conducted at the firm level of analysis is that of Robins and Wiersema (1995), who conducted a study in which they sought to examine the business portfolios of a sample of large US manufacturing firms having multiple businesses. The aim of the study was to determine whether firms that maintained portfolios of relatively similar businesses enjoyed higher financial performance than those firms that maintained portfolios of differentiated businesses. Robins and Wiersema used structural equivalence analyses to model the similarity of businesses in each firm's portfolio. In order to do this, they first calculated the structural equivalence of a set of defined industry categories by using data on technology flows (e.g., patent transfers). In other words, one industry category was considered to be structurally equivalent to another industry category to the extent that they had technology flow ties to the same partners. From these industry-level structural equivalence data, they then created an index for each multibusiness firm in their study that captured the extent of the relatedness of the businesses in its portfolio. A firm was considered to have a highly related portfolio to the extent that each of its businesses were in industry categories that were structurally equivalent with one another. Robins and Wiersema found that the firms with highly related portfolios financially outperformed firms with lower levels of relatedness.

Moving to a lower level of analysis, Padgett and Ansell (1993) analyzed the intermarriage and economic relationships (e.g., trading ties, joint ownerships or partnerships, real estate ties) among families of 15th-century Florence in order to gain insight into the dynamics that led up to the political dominance of the Medicean political party over the reigning oligarch regime in Renaissance Florence. Padgett and Ansell constructed the social networks that existed among 92 elite Florentine families from 1427 to 1434 based on detailed historical accounts of this time. They then computed the structural equivalence of these families and partitioned the network into two structurally equivalent blocks: one affiliated with the Medici family and one affiliated with the oligarch regime. Padgett and Ansell find that their blockmodels are

highly predictive of the political affiliations of each of the families. Padgett and Ansell argue that the social structure uncovered in their analysis is an important factor in understanding how the Medici family was positioned to gain long-lasting political dominance in 1434.

At the individual level of analysis, Burt (1987) examined the effect played by structural equivalence in the diffusion of innovations by reanalyzing the data from Coleman et al.'s (1966) classic study, *Medical Innovation*. In the original study, Coleman et al. (1966) examined the diffusion of the newly released drug tetracycline among a sample of 125 physicians in the midwestern United States in the mid-1950s. Through their analysis of the social networks of these physicians, they concluded that the adoption of the new drug among the physicians was due to informal professional discussions whereby adopter physicians influenced nonadopters through direct contact (i.e., cohesion). Burt (1987) sought to reanalyze these data in order to more thoroughly examine the social structural conditions by which the apparent social contagion effects occurred by incorporating structural equivalence into the analysis. He compared the adequacy of models in which cohesion and structural equivalence were used to predict the adoption behavior of the physicians. Burt concludes that the social contagion effect seen in Coleman et al.'s data is due to structural equivalence, with cohesion having virtually no effect. These results suggest that the physicians in the Coleman et al. study were influenced not by those with whom they had direct interactions, but rather by the adoption behaviors of those with whom they were structurally equivalent. Thus, the results of this reanalysis suggest that one is more likely to feel social pressure to adopt innovations from those who are structurally equivalence as opposed to those to whom one directly interacts with. This study, and others like it (e.g., Burt and Dorian, 1982), provided counterevidence to the long-held belief that the effects of social contagion are explained by cohesion as opposed to structural equivalence. It was one of the first empirical articles to do so, and it gave rise to the debate about whether cohesion or structural equivalence was the primary mechanism through which social contagion occurs (for more on this debate, see Borgatti and Foster, 2003). This study, along with others (e.g., Galaskiewicz and Burt, 1991), provided support for the argument that structural equivalence is of primary importance in social contagion processes.

Structuralism

Abstract

Structuralism is a mode of knowledge of nature and human life that is interested in relationships rather than individual objects or, alternatively, where objects are defined by the set of relationships of which they are part and not by the qualities possessed by them taken in isolation. Claude Lévi-Strauss was the spokesperson for structuralism in Anthropology, incorporating the work of many authors along the twentieth century. Three meanings of 'structuralism' will be distinguished, corresponding to different timescales: structuralism as a French intellectual movement of the 1960s, structuralism as a wider epistemological attitude and Lévi-Strauss' structuralism which is a link between the two.

In a wider sense, structuralism is a mode of knowledge of nature and human life that is interested in relationships rather than individual objects or, alternatively, where objects are defined by the set of relationships of which they are part and not by the qualities possessed by them taken in isolation. Claude Lévi-Strauss was the spokesperson for a structuralist anthropology, but his structuralism incorporated the methods and ideas of predecessors and contemporaries such as Lewis Morgan, for whom the object of the investigation were "systems of relationships" and the "structure of [such] systems" (Trautmann, 2008), A.R. Radcliffe-Brown, who focused on the structure of social relationships instead of individual customs, and E.E. Evans-Pritchard, who dealt with structural time rather than lived time, and the structural forms of clans instead of individual clans. Lévi-Strauss recognized these influences, as well as his debt to Marcel Mauss, the Leiden school and Marcel Granet for the structural analysis of kinship (Hénaff, 1998), and to Georges Dumézil regarding the analysis of myths. In the 1940s, the concept of structure was widespread in social anthropology, which is clear in the works by L. Murdock and C. Lévi-Strauss published in 1949 with the word 'structure' in their titles (Lévi-Strauss, 1967(1949)). However, in contrast with other anthropologists and sociologists who shared structural approaches to human phenomena, Lévi-Strauss explicitly attempted to formulate a structural method and demonstrate its performance through structural analyses conducted in different domains. We will distinguish here three meanings of 'structuralism,' corresponding to different temporal scales: structuralism as a French intellectual movement of the 1960s, structuralism as a wider epistemological attitude who took shape in early nineteenth century, and Lévi-Strauss' structuralism which is a link between the two.

French Structuralism

In the first sense, structuralism refers to an intellectual movement that reached its height in the 1960s in France, with no attachment to any organized group or specific institution. Instead, structuralism was a label for theses associated with R. Barthes, L. Althusser, M. Foucault, and J. Lacan in books following the publication of two seminal books by Claude Lévi-Strauss. These were *The Savage Mind* (1962) and *The Raw and the Cooked* (1964): both were chiefly responsible for placing the movement at the forefront of intellectual debate. This disparate group of *maîtres à penser* can be seen as representative of the French version of the linguistic turn in the Humanities. Faithful to its inspiration in F. De Saussure (rather than in C.S. Peirce or L. Wittgenstein, as in the noncontinental versions), French structuralism focused on 'semiology' as a science that would study 'the life of signs at the heart of social life' in areas such as literature (R. Barthes), philosophy (M. Foucault and L. Althusser), psychoanalysis (J. Lacan), and anthropology (C. Lévi-Strauss). French structuralism was also, in part, a reaction to Jean-Paul Sartre's 'philosophy of the subject,' but it also represented a stance against the empiricism and antimentalism of Anglo-Saxon philosophy. Methodologically, French structuralism emphasized the *system* of signs (synchrony) instead of their history (diachrony), and the *social* character of such systems (*langue*) instead of individual performance (*parole*) (Saussure, 1967(1916), pp. 30–33; Lévi-Strauss, 1950, p. xix), although this characterization has been questioned recently, through the publication of Saussure's original writings (Maniglier, 2006). French structuralism also insisted on the connection between meaning and form or semantics and syntax, again according to Saussure's doctrine of the inseparability of *signifiant* and *signifié* thus distinguishing itself from *formalism* (Lévi-Strauss, 1973, p. 139), and often described structure as systems of binary semantic contrasts, inspired in phonology. Lévi-Strauss distinguished his version 'structuralism' from the 'formalism' of Vladimir Propp's transformational model of folk narratives, which he rejected, as well as F Lounsbury's structural approach, on the grounds of allegedly dissociating 'form' from 'content,' that is to say, dealing in the first case with folktales as sequences of actions and objects without the 'bundles of semantic oppositions' underlying them, and, in the second case, analyzing 'kinship terminology' without 'marriage rules' they are supposed to express (Lévi-Strauss, 1973, p. 139; 1967, p. xxx). N. Chomsky's program of generative linguistics is similarly given short thrift (Lévi-Strauss and Eribon, 1988, p. 160). Philosophically, French structuralists rejected the concept of an autonomous subject endowed with the attributes of freedom to act and to seek knowledge (as in Sartre, 1946), affirming the priority of *structures* over *subjects* (see Caws, 2009 for a reassessment of Sartre as a structuralist). This "destitution of the subject" (Balibar, 2005)

is illustrated by Louis Althusser's formula, "Ideology interpellates individuals as subjects," which condenses the idea that individuals are *made into subjects* by 'State apparatuses' such as family, school, and church. The 'destitution of the subject' as a structuralist trope appears variously as the 'death of the author,' 'structural causality,' 'man is a recent invention,' and in Lévi-Strauss' dictum that "myths think about themselves among themselves … independent of any subject" (Lévi-Strauss, 1964, pp. 19–20). French structuralism proposed to substitute 'unconscious structures' for the 'subject' although the concept of structures that are innate to the human mind (or '*sprit humain*'), or 'immanent' as opposed to self-conscious (Lévi-Strauss, 1950, p. xxxi), does not convey precisely what they consist of or where they are to be located.

Although the rejection of the subject and the refusal of history have been pointed to as diagnostic traits of French structuralism, there are historically oriented versions of structuralism, sometimes allowing for the creative action of subjects. Hellenist Jean-Pierre Vernant, profusely praised by Lévi-Strauss, is a major example (Vernant, 1986). Jean Piaget's 'genetic structuralism' characterizes cognitive structures as relatively stable stages in the development of cognitive abilities which are generated through the interaction between the organism and the environment (Piaget, 1968); Pierre Bourdieu rehabilitated the role of the acting subject, retaining the notion of a structure as schemes for action ("principles of the generation and structuring of practices and representations") embodied in a subject's *habitus*; M Sahlins argued in favor of a view of structure phrased in the Boasian sense of "the symbolic relations of cultural order," as both constraining human practice and being transformed by it (Sahlins, 1985: vii). T. Turner's 'recursively hierarchical' systems of social production and reproduction were proposed as a synthesis of Marxist and epigenetic views of structure, influenced by Piaget's and by French marxism (Turner, 1973). Clearly, there is more to structuralism than is contained in the so-called French structuralism.

Structuralism in Wider Sense

In the wider sense indicated above, structuralism refers to the attitude toward knowledge that has roots within a philosophical and scientific epistemological revolution that took place in the late eighteenth century, represented by G. Leibniz and A. Dürer (Petitot, 2009). In the transition from the eighteenth century to the nineteenth century, W. Goethe formulated the program of a science of 'metamorphoses' or 'transformations,' the goal of which would be nothing short of depicting the underlying formal unity in wide domains of living beings and human works, a seminal idea which was inspired by the Kantian notion of a 'transcendental schema,' which purported to explain how abstract concepts could subsume a virtually infinite variety of particular empirical perceptions (*phenomena*). Goethe's program was invoked by biologist D. Thompson (1992, p. 1032) who argued that similar life forms, such as fish species, could be thought of as related to each other by continuous transformations (Thompson, 1992, pp. 5–7, 1094), although distinct phyla, such as fishes and worms, cannot. Dürer, Goethe, and D'Arcy Thompson, as well as Kant, were thus understandably acknowledged by C. Lévi-Strauss as forerunners of structuralism as a science of 'transformations.' In the 1960s, the Field Medal mathematician R. Thom proposed that his theory of 'morphogenesis' was the appropriate tool for depicting discontinuous changes of form in biological and cultural systems, an idea which J. Petitot applied to Lévi-Strauss's analysis of myths (Thom, 1975(1972); Scubla, 1998; Petitot, 2009). Along another line of thought, Goethe's goal to find a key with which "new plants might be devised *ad itum*" would be realized in Chomsky's concept of a generative grammar (1966)."

Mathematics, which had long been defined as the science of numbers and geometric shapes, came to be seen by the end of the nineteenth century as the study of conceptual-practical structures, the paradigm of which are transformation groups. According to this changed view, groups of transformations embody the notion of what is common in a family of objects, namely, the structural properties which are conserved by the transformations which constitute the group (Weyl, 2012, pp. 170–171). The mathematical concept of a group of transformations was extended to domains such as crystallography, physics, biology, and psychology (Piaget, 1968). It was however with a grain of surprise that it was realized that 'elementary structures of kinship' could be represented as permutation groups, as did André Weil in his invited appendix to Lévi-Strauss treatise (1967(1949)), which was the seed for an extensive body of literature (e.g., White, 1963). Lévi-Strauss came to see this use of modern mathematics to apprehend rules governing marriage rules and kinship terminologies usage as evidence of genuine mathematical ability among illiterate people. It should be mentioned that André Weil's receptivity to Lévi-Strauss's ideas was no accident, as he himself was a forefront member of the group of French mathematicians that, since the 1930s, devoted itself to the task of reconstructing mathematics as a theory of structures under the collective *nom de plume* of Nicolas Bourbaki (1962). According to this research program, groups are the simplest algebraic structure, expressing symmetries and inversions; lattices and trees are examples of structures of order, present in classifications and genealogies, while topological structures involve the notion of continuity and conservation of form.

The Structuralism of Lévi-Strauss

Lévi-Strauss's scientific and literary output ranges from 1945 to 1991. Over the course of nearly half a century, Lévi-Strauss produced three highly influential works, each of which dealt with a distinct domain of ethnographical phenomena: kinship (1945, 1949), classifications (1962a,b), and mythologies (1964, 1966, 1969, 1971; 1979, 1985, 1991). His study of kinship contains a sociological theory based on the concept of exchange, while his theory of mythical throught hinged on the notion of transformation. Coming between these works, *The Savage Mind* was a study of classification, being a philosophical and methodological interlude that launched Lévi-Straussian structuralism into a wider intellectual arena not only as a social theory but also as a philosophy of history and even as a epistemic paradigm. It could be said that the 'mother structures' in the sense the previous section run through the theory

of marriage of *The Elementary Structures of Kinship* (permutation groups), the systems of classification of *The Savage Mind* (taxonomies and conceptual lattices), and the chains of mythical transformations studied in *Mythologiques* (mythical transformations, topological forms such as 'Klein bottles' and Möbius strips). However, there is more to it than that, for according to Lévi-Strauss' insistent reminders, in the course of history events inevitably lead to the loss of structure – a melancholy view of history, which he expressed by borrowing from physics the metaphor of entropy, the assertion of ineluctable and irreversible change from ordered states toward disordered states of any system (Lévi-Strauss, 1967(1949). This view is reasserted in his latest and posthumous writings (Lévi-Strauss, 2013). Lévi-Strauss' analogical borrowing of scientific concepts, however, should be nuanced by the recent appreciation of his importance as a literary artist, influenced by Breton, Mallarmé, and Wagner (Mehlman, 2006) and as a original philosopher, rather than as a scientist strictu sensu (Balibar, 2005; Debaenne, 2008; Viveiros de Castro, 2008; Wyseman, 2009).

Kinship and Group Structures

An early example of Lévi-Strauss's structural approach, algebraic in spirit although phrased with the vocabulary of phonological linguistic, is his article on the 'atom of kinship,' originally published in 1945 (Lévi-Strauss, 1958). The 'atom of kinship' refers to a set of four interconnected relationships, namely husband/wife, brother/sister, father/son, and nephew/maternal uncle, each one associated with an 'attitude,' which Lévi-Strauss characterizes with a '+' or '−' mark. The structural approach consist here in seeking a law behind the patterns in the sets of 'attitudes' found in particular societies, rather than explaining each attitude by social, historical, or psychological causes. This is the proposed law: the husband/wife relationship and the sister/brother relationship have opposite signs, as do the father/son and the avuncular relationships. There are four models which satisfy this requirement: (+/−, +/−), (+/−, −/+), (−/+, +/−), and (−/+, −/+). This model provides an example of group structure known as the Klein group. For let *S* transform (+/−, +/−) into (+/−, −/+) and let *T* transform (+/−, +/−) into (−/+, +/−); *ST* will then be the transformation which takes (+/−, +/−) into (−/+, −/+) and will have the same effect as *TS*. We call the transformation that leaves (+/−, +/−) unchanged the 'identity' *I*. The set of four transformations *I*, *S*, *T*, and *ST* is closed (any composition of transformations is again a transformation) and for each transformation there is an inverse transformation. Lévi-Strauss' own language, the 'family of models' for attitudes within the kinship atom is represented as a group of transformations (Lévi-Strauss, 1958) which preserve as invariant feature the contrast between affinity and consanguinity (the husband/wife and the brother/sister relations have opposite signs, as the maternal uncle/sister's son and the father/son relations do). The structure of the atom of kinship illustrates all the features that Lévi-Strauss listed as being required by 'structural analysis,' and which may be summarized as the specification of the transformations which generate a 'family of models' having in common the same 'pairs of oppositions' (Lévi-Strauss, 1958). It also illustrates the importance of the distinction between empirical data about social relationships and models built up on the basis of those relationships from which structural laws are obtained. Underlying the 'atom of kinship' model there is a social theory according to which kinship is not fundamentally a matter of consanguinity ties of siblingship and filiation, but necessarily includes alliance, either as affinity between in-laws in the same generation, as between brothers-in-law, or across generations, as between nephew and maternal uncle. The contrasted attitudes displayed by the 'atom of kinship' are explained as the necessary opposition between consanguinity and affinity in human social life, which ultimately express the contrast between nature and culture. This thesis is unfolded in Lévi-Strauss's *The Elementary Structures of Kinship*. In Lévi-Strauss's analysis, rules of marriage that prescribe marriage among cross-cousins but forbids it among parallel cousins, as well as kinship terminologies which equate cross-cousins with spouses, are viewed as cultural expressions of an unconscious principle that requires the obligation to give sisters away in order to receive wives from others. In other words, rules and vocabularies are the conscious expressions of unconscious structures of reciprocity. According to Lévi-Strauss, 'elementary structures of kinship' exist in societies where people belong to descent groups, and where the choice of wife is governed by obligatory rules that determine the descent group in which a man can seek a wife. On a more specialized level, Lévi-Strauss classified these 'elementary structures' as two major types. In the first major type, or restricted exchange, women are exchanged reciprocally between paired descent groups, a global, or statistical, social process which the result, at the level of norms regulating individual action, of a rule of marriage according to which a man marries a woman classified as his mother's brother's and as his father's sister's (a bilateral cross-cousin). In the second major type, 'generalized exchange,' women exchange is unilateral, with two possibilities: matrilateral cross-cousin marriage (a man takes for a wife a woman classified as his mother mother's brother's daughter), or patrilateral cross-cousin marriage (a man takes for a wife his father's sister's daughter). Matrilateral cross-cousin marriage leads to cycles of exchange which require several generations to close, in contrast with the short cycles resulting from the patrilateral rule. Such consequences can be be taken as the global results of the strict working of the rules; they may also be seen as statistical effects of the existence of rules that affect the micro-level of individual behavior (Lévi-Strauss, 1967(1949)). Characteristically, such consequences are deduced under the assumption that rules are applied strictly in accordance to a model.

As in the case of the explanation of attitudes between uncles and nephews which motivated the theory of the 'atom of kinship', the explanation of the opposition between cousins and sisters leads theory of social life in which society is depicted as a fabric of exchanges of things and persons, either immediate or along longer circuits. This theory can be seen as an application to the domain of kinship of Marcel Mauss' theory of gift exchange as a basic institution of social integration, which was already present in the work of the Leyden school and Marcel Granet (Héran, 2009, p. 395), and may be compared to economic models of social reproduction through exchange of goods (Rosman and Rubel, 2009).

The interpretation of marriage as exchanges among descent groups leads to the mathematical analysis of elementary

structures a dance of chairs in which lineages or clans interchange the roles of donors and receivers of wives, a clue taken by mathematicians since A. Weil as a sociological version of permutation groups. It should be noted that Lévi-Strauss does not assumes that the real social world must obey the rules in a strict sense; as he made it clear in later writings, he only assumes that social rules, although not followed to the letter, inflect statistical phenomena towards a global picture described by the idealized structure. But the theory of elementary structures is not only formalism, since it also contains the idea that human kinship is based on the insoluble tension between the incestuous desire for autonomy and the cultural obligation of exchange. This tension is a universal human trait for Lévi-Strauss, expressed in the desire to reject the rule of culture and return to an imagined state of nature (Lévi-Strauss, 1967(1949)). This view of culture, where the influence of Freud is clearly seen, is an example of the pessimism that runs through all of Lévi-Strauss's work like a melancholy meta-anthropology: humanity does not have an internal trend toward betterment, but is a result of a nonoriented process throughout which certain structures crystallize in the shorter or longer term, only to dissolve inevitably under the influence of internal contradictions and demographic and environmental change (Lévi-Strauss, 1955). Lévi-Strauss's kinship theory was maybe the part of his opus that fared worst after it formulated in the 1940s, in a empirical sense. His factual basis was contested early on by E. Leach (1961), while Lévi-Strauss himself noted in 1967 that 'elementary structures' as social systems for the regulation of marriages, implying unilineal descent according to his definition, were relatively rare in the world where cognatic systems are more frequent (Lévi-Strauss, 1967). The notion of cross-cousin marriage as the basic form of alliance was also subject to criticism for not accounting for cases as 'Arab marriage,' a prescribed union between paternal parallel cousins (Barry, 2000; Coelho de Souza, 2009). Recent research movements focused on modeling real social relationships through graph theory can be seen as a mode of structural analysis by means of rigorous analysis and ethnography (Hamberger et al., 2011).

Savage Thought: Structures of Order

The broader impact of Lévi-Strauss's work was not a consequence of his 1949 study of kinship, although it was at once reviewed by Simone de Beauvoir (who praised it, pace later feminist critiques) and received a detailed critique by Jean-Paul Sartre, as well as awakening the sympathies of philosopher Merleau-Ponty. Lévi-Strauss's ideas broke through national and academic borders through *La Pensée Sauvage*, later translated as *The Savage Mind* – a multifaceted book containing general ideas about science, art, and the science of nonliterate peoples, a theory of totemism and classification systems, and a polemical, nonteleological view of history. Whereas in the decades between the 1940s and 1960s Lévi-Strauss introduced the structural method as an extension of the scientific use of models in the humanities, *The Savage Mind* emphasizes the idea that 'savage' or untamed thought is another form of scientific thought, which amounts to say, is capable of applying logical reasoning to sense perception. He pictured this idea through the famous analogy of the *bricoleur*, a tinker who builds structured object out of fragments found haphazardly and with no previous master plan. Such objects, be they myths or kinship terminologies, body paintings or musical pieces, technical artifacts or domesticated plants, are according to this view both historical objects and mental constructions, and therefore the same time contingent and subject to constraints. Lévi-Strauss extols the inventions and techniques of the 'Neolithic revolution' as lasting results of the workings of such '*science du concret*' in the past, at the same time reminding us that this creative mind is currently active in traditional knowledge and art. *The Savage Mind* gave a detailed account of how this science of illiterate people was active in conceiving complex classification systems encompassing plants, animals, people, and cosmic phenomena. Classification systems are by no means mere sets of 'binary oppositions,' as in the 'atom of kinship' model, or permutation groups as in the 'elementary structures' form. They involve *order structures*, described by mathematicians as 'conceptual lattices' or as 'formal ontologies,' which attempt to show relations of inclusion and implication between categories (Lévi-Strauss, 1962, p. 201; Parrochia and Neuville, 2013, p. 30). The investigation of 'savage thought' as wide-reaching modes of classifying the human and natural worlds was pursued by P. Descola (2005).

It has been said that *The Savage Mind* contains a cybernetic theory of social stability essential for structuralism: according to this interpretation, the classificatory 'structures' there described are regulatory devices to ensure social stability (Bloch, 1996, p. 531). This view is apparently anchored in Lévi-Strauss's contrast between 'cold' and 'hot' societies, the first seeking to 'annihilate time' and retain structures, the latter valuing change and accumulation; however, as a theory of history, this view is contradicted by Lévi-Strauss insistence on the idea that every society and every symbolic system is subject to 'entropy,' to inevitable degradation of the structure over time (Lévi-Strauss, 1955). One example is myths, which not only transform into each other, but may lose their structure and eventually die at the end of long transformational trajectories and in contact with other narrative systems.

Myths: Transformations and Continuity

Lévi-Strauss devoted his longest study to the structural analysis of the myths of the Americas, both in the *Mythologiques* (published in four volumes from 1964 to 1971) (Lévi-Strauss, 2008; comprising three independent little volumes originally published from 1979 to 1991). These analyses give rise again to a new way of employing structural analysis. Instead of finite models having the structure of groups, one is now confronted with myths connected by an open set of transformations. Thus, close to a 1000 myths that extend from the Chaco region of South America to Canada are viewed as part of chains of transformations, both historical-geographic and logical-metaphysical. Furthermore, in this work, Lévi-Strauss takes to the extreme his tendency to attribute the same dignity to the construction of myths as he does to scientific and artistic works: mythical thinking is the work of a collective author, persistently tackling themes of essential interest for the Amerindian mind, such as the relationship between the cosmic, terrestrial, and subterranean planes of life, as well as the opposition between animals and humans, cultural and natural objects, the

continuous and the discrete, the finite and the infinite. One can found an almost didactic example of Lévi-Strauss's use of the 'transformation' concept in the opening chapters of *The Jealous Potter*, one of the "small mithologiques," where Lévi-Strauss provides a detailed commentary on a set of myths from the South American Jivaro Amerindians that suggests clues to "the place of jealousy in myths on the origins of pottery," connecting "an art of civilization, a moral sentiment and a bird" (Lévi-Strauss, 1985, p. 32; Gow, 2009). This assertion is argued by Lévi-Strauss as follows. He firsts shows that myths recorded for the Jivaro area assert a connection between the art of pottery, jealousy and a bird, the Night-Hawk. These 'empirically' recorded connections (in myth narratives) suggest that there should be a bird linking pottery and conjugality. Or, as Lévi-Strauss reconstructs the mythical reasoning at play: as a *jealous* bird (Night-Hawk) is related to the *pottery-making* ability of Woman, the Woman's *jealousy* should be related to a *pottery-making bird*. The problem, says Lévi-Strauss, is that there is no such bird in the Achuar área – namely, a bird with the required in the set of myths available in the Achuar area. This situation 'puts certain fundamental principles into play in the structural analysis of myth.' And this is the fundamental principle: given a logically incomplete set of myths, we must seek a missing piece in *another* sets of myths, perhaps in nearby geographical settings, perhaps in another semantic context, in which the mythical reasoning comes to a closure. Let us illustrate this mechanism: Lévi-Strauss finds a conclusion of the logical sequence initiated in the Peruvian rain forest in myths recorded in the Chaco plains, where there is indeed a pottery-making bird, the *Oven-bird*. While the Night-Hawk is a jealous and lonely bird that cries on moonlit nights remembering his lost cosmic partner, the oven-bird is a happily married bird that lives in a house he built from clay together with his wife. In Lévi-Strauss's terms, the *Oven-bird* is a 'transformation' of the *Night-Hawk* that preserves the logical structure underlying the explanation of the origins of pottery, while connecting two different ecological setting, that of the Peruvian pre-andean rain forest and that of the Chaco plains. In sum, the analysis of myths must combine 'empirical deductions,' that is, those which are based directly on the mythical material, and 'transcendental deductions' that make it possible to "close a cycle of transformations" (Lévi-Strauss, 1985, p. 80).

Myths transform themselves in history (Gow, 2001) and are geographically connected by a process of dissemination that is, however, obliged to follow logical procedures (Carneiro da Cunha, 1973). It has been argued that the mythical transformations invoked by Lévi-Strauss are closer to the grammar of dreams and to surrealistic aesthetics than to formal logic (Viveiros de Castro, 2008). Instead of the turalism of binary pairs that form closed and finite groups, we find here, according to a post-modern interpretation of Lévi-Strauss' views pioneered by Viveiros de Castro, a situation where "the subject is always a particular state of a system of transformations whose boundaries are radically contingent," and in which the concept of structure "does not favor any desire for closure, completion or compactness" (Viveiros de Castro, 2008). These characteristics are particularly supported by *Story of Lynx*, the last work that Lévi-Strauss devoted to the analysis of myths (Lévi-Strauss, 1991). In it, the author explains that 'binary pairs' are just a particular example of 'transformations' that include inversions, equivalencies, symmetries, and contradictions (pp. 249ff.); that transformations occur along multiple semantic axes that include time and space, the body and stars, sexuality and cuisine; finally, that 'transformation' can take place 'by degrees,' that 'unstable dualism' is the rule, that mythological systems are in a state of 'perpetual imbalance,' and that mythological transformations are therefore open (pp. 306–316). Furthermore, mythological transformations do not appear as the product of a mythical mind floating in space, but as the work of myth builders whose work must respect the historical boundaries imposed by the settlement of the Americas. Mechanical and symmetrical group structures can occur locally, but in the overall analysis, they give way to irreversible historical processes such as the colonization of the America.

The Legacy of Structuralism

Structuralism was the target of criticisms that demanded either a return to history to the detriment of 'synchrony,' a return to 'thick ethnography,' preferably to the pursuit of doces,' or a rehabilitation of the active and revolutionary subject from his alleged position of an 'effect' of structures (Turner, 1973, 2009). The influence of structuralism remained strong among specialists in lowland South America, where Lévi-Strauss had his original ethnographic experience. Vigorous research programs on the social structure of indigenous societies of Central Brazil were conducted in dialogue with his theses although in a critical vein (Maybury-Lewis, 1979). Carneiro da Cunha pointed to the role of mythical structures dealing with messianic movements in Amazonia (1973) and of the connection between structure and the *persona*; S. Hugh-Jones (1979b) and C. Hugh-Jones (1979a) have shown how a close ethnography of ritual and body practices could be framed in structuralism terms, while P. Gow demonstrated the possibility of combining a historical-biographical approach with the structural analysis of myths (Gow, 2001, 2009). E. Viveiros de Castro is a foremost example of Lévi-Strauss' influence on contemporary South American anthropological thinking, combined with a Deleuzian 'post-structural' twist (Viveiros de Castro, 1992), while P. Descola has developed a wide-ranging theory of sociocosmologies rooted in the structuralist heritage (Descola, 2005).

In a more general sense, what is left of structuralism in the twenty-first century? Perhaps the notion that the world of natural and human phenomena can either be scrutinized in depth toward the complexity of particular objects – whether a painting or a novel, an equation or an animal species, a year in history and a village in the country, a concept or a musical piece – or analyzed in pursuit of generality and abstraction, placing the individual thing so speak within a set of variations on a same theme. In this sense, both 'French structuralism' with its mentalist tradition and literary style and 'British structuralism' with its adherence to empirical sobriety are as many varieties of the encompassing nineteenth-century epistemological strive for generalization and model building which made its marks in sciences, humanities, and arts along the twentieth century, and was since then not so much refuted as assimilated to the point of becoming a set of truisms in domains such as social network

analysis, having been thus incorporated into common sense, structuralism may be as well be forgotten.

Abstract

Subaltern Studies is a series of writings on modern South Asian history in which Antonio Gramsci's idea of the subaltern classes was used to study the autonomous struggles of peasants in colonial India. Even when peasants participated in movements led by nationalist elites, they retained their own objectives, methods, and ideologies. Since there were few written sources produced by peasant activists themselves, and since elite sources usually depicted the subaltern as passive and subservient, subalternist historians argued that the forms of autonomous subaltern consciousness were best revealed in the archives of peasant revolt. The idea of autonomous subaltern consciousness was criticized, following which the project reoriented itself to consider several other facets of subaltern life in which elite and subaltern domains were intertwined. This included topics such as religion, caste, gender, nationalism, modernity, etc. An important feature here is the argument that Western modernity, encountering resistance from subaltern practices in South Asia, were taking the shape of different and hybrid modernities.

Gramsci in India

In the form in which it is currently known, subaltern historiography is derived from the writings of a group of historians of modern South Asia whose work appeared between 1982 and 2005 in a series of 12 volumes entitled *Subaltern Studies* (Amin and Chakrabarty, 1996; Arnold and Hardiman, 1994; Bhadra et al., 1999; Chatterjee and Jeganathan, 2000; Chatterjee and Pandey, 1992; Guha, 1982–1989; Mayaram et al., 2005). The term 'subaltern' was borrowed by these historians from Antonio Gramsci, the Italian Marxist, whose writings in prison in the period 1929–35 had sketched a methodological outline for a 'history of the subaltern classes' (Gramsci, 1971). In these writings, Gramsci uses the word 'subaltern' (*subalterno* in the Italian) in at least two senses. In one, he used it as a code for the industrial proletariat. But against the thrust of orthodox Marxist thinking, he emphasized that in its rise to power, the bourgeoisie did not simply impose a domination through the coercive apparatus of the state but transformed the cultural and ideological institutions of civil society to construct a hegemony over society as a whole, even eliciting in the process the acquiescence of the subaltern classes. In Gramsci's analysis of capitalist society, the central place is occupied by questions such as the relation of state and civil society, the connections between the nation; the people; the bourgeoisie; and other ruling classes, the role of intellectuals in creating the social hegemony of the bourgeoisie, strategies for building a counterhegemonic alliance, etc.

In the second sense, Gramsci talked of the subaltern classes in precapitalist social formations. Here he was referring to the more general relationship of domination and subordination in class-divided societies. But specifically in the context of southern Italy, he wrote about the subordination of the peasantry. Gramsci was very critical of the negative and dismissive attitude of European Marxists toward the culture, beliefs, practices, and political potential of the peasantry. Positioning himself against this attitude, he wrote of the distinct characteristics of the religious beliefs and practices, the language and cultural products, the everyday lives and struggles of peasants, and of the need for revolutionary intellectuals to study and understand them. But he also highlighted the limits of peasant consciousness, which in comparison with the comprehensiveness, originality, and active historical dynamism of the ruling classes, was fragmented, passive, and dependent. Even at moments of resistance, peasant consciousness remained enveloped by the dominant ideologies of the ruling classes. These discussions by Gramsci were turned to productive use by South Asian historians writing in the 1980s.

Against Elitist Historiography

Ranajit Guha, who edited the first six volumes of *Subaltern Studies*, wrote in the introductory statement of the project: "The historiography of Indian nationalism has for a long time been dominated by elitism – colonialist elitism and bourgeois-nationalist elitism" (Guha, 1982). The objective of subaltern historiography was to oppose the two elitisms. The field of modern South Asian history was dominated in the 1970s by a debate between a group of historians principally located in Cambridge, UK, and another based mainly in Delhi, India. The former argued that Indian nationalism was a bid for power by a handful of Indian elites who used the traditional bonds of caste and communal ties to mobilize the masses against British rule. The latter spoke of how the material conditions of colonial exploitation created the ground for an alliance of the different classes in Indian society and how a nationalist leadership inspired and organized the masses to join the struggle for national freedom. Guha argued that both these views were elitist – the former representing a colonial elitism and the latter a nationalist elitism. Both assumed that nationalism was wholly a product of elite action. Neither history had any place for the independent political actions of the subaltern classes.

In setting their agenda against the two elitisms, the historians of *Subaltern Studies* focused on two main issues. One was the difference between the political objectives and methods of colonial and nationalist elites on the one hand and those of the subaltern classes on the other. The second was the autonomy of subaltern consciousness. Pursuing the first question, the historians of *Subaltern Studies* showed that the claim of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.62129-3

colonialist historians that the Indian masses had been, so to speak, duped into joining the anticolonial movement by Indian elites using primordial ties of kinship and clientelism was false. They also showed that it was untrue to say, as nationalist historians did, that the political consciousness of the subaltern classes was only awakened by the ideals and inspiration provided by nationalist leaders. It was indeed a fact that the subaltern classes had often entered the arena of nationalist politics. But it was also a fact that in many instances they had refused to join, despite the efforts of nationalist leaders, or had withdrawn after they had joined. In every case, the goals, strategies, and methods of subaltern politics were different from those of the elites. In other words, even within the domain of nationalist politics, the nationalism of the elites was different from that of the subaltern classes.

The second question followed from the first. If subaltern politics was indeed different from that of elite politics, what was the source of its autonomy? What were the principles of that politics? The answer that was suggested was that subaltern politics was shaped by the distinct structure of subaltern consciousness. That consciousness had evolved out of the experience of subordination – out of the struggle, despite the daily routine of servitude, exploitation, and deprivation, to preserve the collective identity of subaltern groups. Where was one to look for the evidence of this autonomous consciousness? It could not be found in the bulk of the archival material that historians conventionally use, because that material had been prepared and preserved by and for the dominant groups. For the most part, these documents only show the subaltern as subservient. It is only at moments of rebellion that the subaltern appears as the bearer of an independent personality. When the subaltern rebels, the master realizes that the servant too has a consciousness – interests and objectives, methods and organization. If one had to look for evidence of an autonomous subaltern consciousness in the historical archives, then it would be found in the documents of revolt and counterinsurgency.

The first phase of the work of *Subaltern Studies* was dominated by the theme of peasant revolt. Ranajit Guha's *Elementary Aspects of Peasant Insurgency in Colonial India* (1983) is the key text in this area. But most other scholars associated with the project wrote on the history of peasant revolts from different regions and periods of South Asian history. They were able to discover a few sources where the subaltern could be heard telling his or her own story. But it was always clear that there would be few such sources. What became far more productive were new strategies of reading the conventional documents on peasant revolts. The historians of subaltern politics produced several examples of ways in which reports of peasant rebellion prepared by official functionaries could be read from the opposite standpoint of the rebel peasant and thus used to shed light on the consciousness of the rebel. They also showed that when elite historians, even those with progressive views and sympathetic to the cause of the rebels, sought to ignore or rationally explain away what appeared as mythical, illusory, millenarian, or utopian in rebel actions, they were actually missing the most powerful and significant elements of subaltern consciousness. The consequence, often unintended, of this historiographical practice was to somehow fit the unruly facts of subaltern politics into the rationalist grid of elite consciousness and make them understandable in terms of the latter. The autonomous history of the subaltern classes, or to put it differently, the distinctive traces of subaltern action in history, were completely lost in this historiography.

The Imbrication of Elite and Subaltern Politics

The analysis of peasant insurgency in colonial India and of subaltern participation in nationalist politics by the historians of *Subaltern Studies* amounted to a strong critique of bourgeois-nationalist politics and the postcolonial state. Writing about peasant revolts in British India, Ranajit Guha (1983) and Gautam Bhadra (1994) showed how this powerful strand of anticolonial politics, launched independently of bourgeois-nationalist leaders, had been denied its place in established historiography. Gyanendra Pandey (1984, 1990), David Hardiman (1984), Sumit Sarkar (1984), and Shahid Amin (1995) wrote about the two domains of elite and subaltern politics as they came together in the nationalist movement led by the Congress. Dipesh Chakrabarty (1989) wrote about a similar split between elite and subaltern politics in the world of the urban working class. Partha Chatterjee (1986, 1993) traced the development of nationalist thought in India in terms of the separation of elite and subaltern politics and the attempts by the former to appropriate the latter. The post-colonial nation-state had, it was argued, included the subaltern classes within the imagined space of the nation but had distanced them from the actual political space of the state. Although the political emphasis was not the same in each writer, there was nevertheless a strong flavor in *Subaltern Studies* of the Maoist politics that had hit many parts of India in the 1970s. Many critics thought they could detect in it a romantic nostalgia for a peasant armed struggle that never quite took place. Others alleged that by denying the unifying force of the nationalist movement and stressing the autonomous role of the subaltern classes, the historians of *Subaltern Studies* were legitimizing a divisive and possibly subversive politics (see Ludden, 2001).

Another connection that was often made in the early phase of *Subaltern Studies* was with the 'history from below' approach popularized by British and French historians. Clearly, the work of British Marxist historians and the *Annales* school was eagerly mined by subalternist historians for methodological clues for doing popular history. But there was a crucial difference because of which subaltern history could never be a 'history from below.' The forgotten histories of the people, pulled out from under the edifice of modern capitalist civilization in the West, had undoubtedly made the story of Western modernity more detailed and complete. But there did not seem to be any narrative of 'history from below' that could persuasively challenge the existence, stability, or indeed the historical legitimacy of capitalist modernity itself. Not surprisingly, 'history from below' was invariably written as tragedy. But in countries such as India, 'history from below' could not be confined within any such given narrative limits. The subalternist historians refused to subscribe to the historicist orthodoxy that what had happened in the West, or in other parts of the world, had to be repeated in India. They rejected the framework of modernization as the necessary emplotment of history in the formerly colonial countries. They were skeptical about the established

orthodoxies of both liberal nationalist and Marxist historiographies. As a result, they resisted in their writings the tendency to construct the story of modernity in India as the actualization of modernity as imagined by the great theorists of the Western world. This resistance, apparent even in the early phase of *Subaltern Studies*, was to be expressed later in arguments about 'other modernities.'

Reorientations

One line of argument of the early *Subaltern Studies* project that ran into serious problems concerned the existence of an autonomous subaltern consciousness. Much of the study of the insurgent peasant was a search for a characteristic structure of peasant consciousness, shaped by its experience of subordination but struggling ceaselessly to retain its autonomy. One problematic question that arose was about the historicity of this structure. If subaltern consciousness was formed within specific historical relations of domination and subordination, then could that consciousness change? If so, why could it not be said that the Indian peasantry was transformed, modernized, turned into citizens by its experience of nationalist politics? Or was there another narrative of a changing subaltern consciousness? It was a classic structuralist impasse to which there was no easy historical answer.

A related problem was about the notion of the subaltern as an active historical agent. Research into subaltern history had shown that the subaltern was both outside and inside the domains of colonial governance and nationalist politics. To the extent that it was outside, it had retained its autonomy. But it had also entered those domains, participated in their processes and institutions and thereby transformed itself. Every bit of historical evidence was pointing to the fact that the subaltern was 'a deviation from the ideal.' Why then the search for a 'pure structure' of subaltern consciousness? Moreover, argued Gayatri Spivak (1987, 1988) in two influential articles, subaltern history had successfully shown that the 'man' or 'citizen' who was the sovereign subject of bourgeois history writing was in truth only the elite. Why was it necessary now to clothe the subaltern in the costume of the sovereign subject and put him on stage as the maker of history? Subaltern historiography had in fact challenged the very idea that there had to be a sovereign subject of history possessing an integral consciousness. Why bring back the same idea into subaltern history? It was only a myth that the subaltern could directly speak through the writings of the historian. In fact, the historian was only representing the subaltern on the pages of history. The subaltern, announced Spivak, cannot speak.

The new turn in *Subaltern Studies* began more or less from the fifth and sixth volumes published in 1987–89. It was now acknowledged with much greater seriousness than before that subaltern histories were fragmentary, disconnected, incomplete, split within itself, and constituted by elements drawn from the experiences of both dominant and subordinate classes. Alongside the evidence of autonomy displayed by subalterns at moments of rebellion, the forms of subaltern consciousness undergoing the everyday experience of subordination now became the subject of inquiry. Once these questions entered the agenda, subaltern history could no longer be restricted to the study of peasant revolts. Now the question was not 'What is the true form of the subaltern?' The question had become 'How is the subaltern represented?' 'Represent' here meant both 'present again' and 'stand in place of.' Both the subjects and the methods of research underwent a change.

One direction in which the new research proceeded was the critical analysis of texts. Once the question of the 'representation of the subaltern' came to the fore, the entire field of the spread of the modern knowledges in colonial India was opened up for subaltern history. Much studied aspects such as the expansion of colonial governance, English education, movements of religious and social reform, the rise of nationalism – all of these were opened to new lines of questioning by the historians of *Subaltern Studies*. The other direction of research concentrated on the modern state and public institutions through which modern ideas of rationalism and science and the modern regime of power were disseminated in colonial and postcolonial India. In other words, institutions such as schools and universities, newspapers and publishing houses, hospitals, doctors, medical systems, censuses, the industrial labor process, scientific institutions – all of them became subjects of subaltern history writing.

Other Modernities

A major argument that has been developed in the more recent phase of writings in and around *Subaltern Studies* is that of alternative or hybrid modernities. The focus here is on the dissemination of the ideas, practices, and institutions of Western modernity under colonial conditions. The framework of modernization theory invariably produces the history of modernity in non-Western countries as a narrative of lag or catching up. As Chakrabarty (2000) has put it, these societies seem to have been consigned forever to 'the waiting room of history.' The universality of Western modernity erases the fact that like all histories, it too is a product of its local conditions. What happens when the products of Western modernity are domesticated in other places? Do they take on new and different shapes – shapes that do not belong to the original? If they do, are we to treat the changes as corruptions? As deviations from an ideal? Or are they valid as examples of a different modernity?

To argue the latter is both to provincialize Europe and to assert the identity of other cultures even as they participate in the presumed universality of modernity. Chakrabarty (2000), Arnold (1993), Prakash (1999), and Spivak (1999), for example, have explored various aspects of this process of the 'translation' of modern knowledges, technologies, and institutions. They have tried to show that the encounter between Western forms of modernity and non-Western cultures was not a simple imposition of the one on the other, nor did it lead to corrupt or failed forms of modernity. Rather, it produced different forms of modernity whose marks of difference still remain subject to unresolved contestations of power. Kaviraj (2005) observed that the process of translation was better understood as involving different historical sequences of modernity in which its constitutive elements were serially produced in different countries, leading to different end products.

Here, the work of South Asian subalternist historians often overlapped with and contributed to what has become known as postcolonial studies. The historical study of modern discourses and institutions of power in colonial India fed into a growing literature on the production of hybrid cultural forms in many different regions of the formerly colonial world. More significantly, postcolonial studies extended the argument about hybrid cultural forms to the understanding of contemporary cultures in the Western metropolitan countries themselves, instanced most immediately in the diasporic cultures of immigrants but also, less obviously, in the role of the colonial experience in the formation of Western modernity even in its purportedly 'original' form.

Rethinking the Political

What then is the current understanding of subaltern politics? The early emphasis on peasant rebellion and consciousness had widened, even in the first phase of the project, to include the resistance of other dominated and marginalized groups in colonial society. Once the idea of a paradigmatic structure of subaltern consciousness became less persuasive, the subject of resistance began to be approached from a variety of angles and without a fixed design either of the reproduction of a traditional structure or of the necessary transition to new structures. Recent subaltern historiography has vigorously participated in three sets of South Asian debates – over religious minorities, caste, and gender. These debates have opened up the way to rethinking the political formation of the nation as well as the political process of postcolonial democracy.

In South Asia, the broader political debate over religious minorities has been carried out between two opposed groups – Hindu and Muslim chauvinists on the one hand and the secularists on the other. What the researches of subalternist historians have shown is that the debate between secularism and communalism is in no way a struggle between modernity and backwardness. Both the rival political positions are firmly planted in the soil of modern government and politics. Second, the two groups are pursuing two different strategies of consolidating the regime of the modern nation-state. Both strategies are elitist. But they involve two different modes of representation and appropriation of the subaltern. Third, faced with these rival elitist strategies, subaltern groups are devising, in their own ways, independent strategies of coping with communal as well as secularist politics. Recent experiences of ethnic violence and authoritarian politics in Sri Lanka and Pakistan have raised even more fundamental questions about the adequacy of the nation-form as a field where subaltern politics might be negotiated (Chatterjee and Jeganathan, 2000).

The second question on which there has been significant recent discussion is caste. There has been a transformation in the politics of caste in India following the agitations in 1990–91 over the Mandal Commission report. By looking at the politics of caste in its discursive aspect, it has become clear that the supposedly religious basis of caste divisions has now completely disappeared from public debate. The conflicts now are almost exclusively centered on the relative positions of different caste groups in relation to the state. Second, the debate over whether or not to recognize caste as a criterion of affirmative action by the state once again reflects two different elitist strategies of representing and appropriating the subaltern. And subaltern groups too, in their efforts to establish social justice and self-respect, are devising various strategies of both resisting the state as well as of using the opportunities offered by its electoral and developmental functions. Strategies of alliance of lower castes with middle or upper castes or with other oppressed groups such as tribals and religious minorities have produced significant electoral successes. But with the creation of new political elites out of subaltern groups, the questions of 'who represents?' and 'to what end?' are being asked with a new urgency (Mayaram et al., 2005).

The third debate concerns the social position of women. In one sense, all women living in patriarchal societies are subalterns. Yet it is not true that women are not identified by class, race, caste, and community. Hence, just as it is valid to analyze the subordination of women in a society ruled by men, so also is it necessary to identify how the social construction of gender is made more complex by the intervention of class, caste, and communal identities. Recent discussions on the question have focused on the Indian social reform movements of the nineteenth century, especially the various legal reforms to protect the rights of women, in the context of the colonial state and nationalist politics. Subaltern feminist writings have raised questions about the adequacy of a modernizing agenda of legal reform from the top without facing up to the challenge of reforming the actual structures of patriarchal power within the local communities that continue to flourish outside the reach of the law.

The recent debates have raised new questions about conceptualizing old ideas such as nation, citizenship, and democracy. The forms of subaltern participation in governmental processes and electoral politics in postcolonial democracies are now being conceptualized as modalities of democratic practice unknown in Western democracies (Chatterjee, 2004, 2011). By virtue of these implications, the recent subaltern history writings from South Asia have been productively used in writings on the history of modernity in other parts of the formerly colonized world, such as, for instance, on nationalism and gender in the Middle East or on the politics of peasant and indigenous groups in Latin America. Having traveled from Italy to India, the idea of subaltern history has now produced a generally available methodological and stylistic approach to modern historiography that could be used anywhere.

Abstract

In this article, 'subculture' is defined simply as a culture embedded within a broader culture. Despite theoretical debates concerning its usage within the two main schools of thought, the Chicago School and the Birmingham Centre for Contemporary Cultural Studies, the concept remains important. Discussion of the underlying unity of conceptualizations and their variation invites reflection on the development of research on subculture and also foreshadows its future. Consideration of the emergence of similar terms, some proposed as replacements to subculture, and of the benefits of the application of such terminology, suggests pathways for future research. Specific issues include the changing relevance and understanding of subculture with advancing technology, as well as the insights to be gleaned from the related literature on community. This article concludes with a discussion of methodological approaches used to study subculture, with considerations for the future of its conceptualization and study in an increasingly digital age.

Introduction

In the most general sense, a 'subculture' is a culture embedded within a broader culture. The terminology used here is purposefully vague. This definition does not, for example, stipulate the relationship between a subculture and the broader culture in which it is embedded; it does not specify whether they are distinctly different, share some similarities, coexist in harmony, or are in conflict with each other. Furthermore, this definition does not describe the relationships among members of the subculture, whether they interact only online, sometimes see each other face-to-face, know each other, or are strangers. Thus, though extremely basic, this simple definition of a subculture as a culture within another culture seems the most reasonable place to start this article, especially given the degree to which the concept has been debated historically. This initial simplicity does not deny the complexities, controversies, and challenges bound to the concept of 'subculture,' but to circumvent these issues, focuses on 'culture' as its defining feature.

Honing in on culture provides an entrée into this discussion of subculture. Despite slight variations in terminology specified and prioritized, most social science textbooks provide a definition of 'culture' as resting upon a foundation of certain elements. Elements commonly included as part of this list are beliefs, values, norms, customs, rituals, ideas, knowledge, physical artifacts, language, symbols, and gestures. Often, these elements are separated into those that constitute material culture (physical and material objects) and those that constitute nonmaterial culture (values, norms, etc.). These disparate elements are united by a web of meanings shared by the members of a culture, or more pertinent here, by the members of a subculture. Thus, to elaborate on the basic definition of subculture provided here, we can now add that a subculture finds its distinction from another subculture or from the broader culture on the basis of these same disparate elements and the meanings attributed to them differing to some degree.

At this point the simplicity of this definition begins to dissolve. The difficulty in unpacking this definition any further arises from the problem of operationalizing the notion of difference. The question becomes how different and how self-consciously different a social group must be in order to be considered distinct. Establishing such parameters has become more problematic as our world has become increasingly globalized and as modern technological advancements in information, communication, and transportation have served to erode temporal and geographic boundaries that once confined the members of social groups to shared times and spaces (Adams, 1998). Descriptions that define a subculture as a distinct culture from a dominant culture have grown less relevant in a postmodern age in which templates of cultural hierarchies have at the least become blurred, if not identifiable as entirely historically inaccurate and useless. Furthermore, the notion of a dominant culture has long been critiqued for implying 'normalization' through which subcultures have often been narrowly cast as deviant, whether subtly or overtly.

Yet, despite the challenges of defining subculture and questions regarding the ongoing relevance of the concept, studies of subculture have clearly added to the understanding of society. Studying subcultures has allowed both a detailed and nuanced perspective on cultural groups not necessarily well known or understood by the 'mainstream' (as the larger, dominant culture is often called) and at the same time has provided a broad and inclusive approach in terms of recognizing instead of ignoring these distinct groups. The study of subcultures thus provides a more realistic picture of a society by recognizing complex layers of divergent groupings within it. For, as is the case given the nature of humans and humanity, as long as societies have existed, so too have a variety of ways of building culture within them. This necessarily social process of providing meaning to that existence will inevitably vary in form and expression across different societies and social groupings.

Furthermore, although much of the research on subcultures focuses on social groups within the English-speaking world,

culturally distinct groups exist within all societies. In other words, subcultures have been present throughout time (i.e., history) and across space (i.e., the globe); the elements of subcultures have been transmitted from one generation to the next and diffused across geographic boundaries. Subcultures serve as the basis for individual identity and group solidarity, which in turn leads to both social integration and intergroup dynamics. Not only are subcultures intrinsic parts of societies and thus important to study, but doing so has also allowed for the recognition, understanding, and sometimes even acceptance or appreciation of these social groups, which has had important consequences, especially for those subcultures that were considered deviant and consequently were marginalized (e.g., see Decade in Brief (2012) for a discussion of the Decade of Roma Inclusion 2005–15, "an unprecedented political commitment by European governments to eliminate discrimination against Roma and close unacceptable gaps between Roma and the rest of society").

Theoretical Issues: The Definition of Subculture

Despite the initial simplistic definition, and the undeniable value of studying subcultures, the trajectory of its use in the social sciences has not been so straightforward. Although two main schools of thought have dominated conceptualizations of subculture – the Chicago School and the Birmingham Centre for Contemporary Cultural Studies (CCCS) – so too have the critiques of these conceptualizations.

Yet, despite the debates that have come to hallmark the term, questioning its validity and even arguing against its relevance, beneath this divergence is an arguably unified understanding of the term. In other words, while broadened and narrowed, expanded, and simplified, and redirected and refocused, the various conceptualizations of subculture have nonetheless generally unfolded within a shared framework. Although early anthropologists used the term to mean universal tendencies that occur in all societies (e.g., Linton, 1936), that definition was later eclipsed by broader ones resting on such facets as those discussed earlier in this entry; an example is "normative systems of groups smaller than a society, to give emphasis to the ways these groups differ in such things as language, values, religion, diet, and style of life from the larger society of which they are a part" (Yinger, 1960: p. 626). Chicago School sociologists popularized this type of definition in research to explain deviant behavior, arguing that behavior perceived to be deviant from a mainstream perspective could be in keeping with the norms of a smaller group within society (Becker, 1963; Matza and Sykes, 1961). As early as 1960, Yinger noted that a third definition of subculture as determined by "norms that arise specifically from a frustrating situation or from conflict between a group and a larger society" had also been used in the literature; rather than recommending the element of conflict be incorporated into the definition of subculture, he suggested these subcultures be designated as 'contracultures' to distinguish them from subcultures that existed more harmoniously with the mainstream (Yinger, 1960: p. 629).

This distinction between subcultures and contracultures continued to be recognized in much of the research that was conducted in the 1960s and 1970s (e.g., Dorn, 1969; Kando, 1975; Rich, 1972; Sebald, 1975); the two notions were not reconflated until the CCCS began its research on post–World War II working-class youth subculture. Although building on Chicago School studies of deviant subcultures, the publication of *Resistance through Rituals* (Hall and Jefferson, 1976) and *Subculture: The Meaning of Style* (Hebdige, 1979) shifted the discussion from an examination of the patterns across a variety of deviant subcultures to a societal perspective on the ongoing class struggle in Great Britain and the stylistic responses of youth.

Although some scholars have continued to apply the more general definition of subculture in their work on youth subcultures (e.g., Hunt, 2008, 2010; Latysheva, 2011), and especially in examinations of subcultures not associated exclusively with youth (Lieske, 2004; Spencer, 1997), after the introduction of the notion of youth subcultures as 'cultures of resistance,' this more specified definition has dominated the subculture literature and much of the critique of the notion of subculture since then is a response to this more specific usage (e.g., Crosset and Beal, 1997; Miles, 2000; Straw, 1999). Muggleton and Weinzierl (2003), for example, question the validity of this approach in a postmodern world, and champion "a more pragmatic approach compared to the romanticism of the CCCS" (p. 4). Short of a direct critique, others have suggested moving beyond this narrow scope, such as Fincham (2007), who champions the aspect of 'enjoyment,' as one often overlooked as an attraction to membership in a subculture. Interestingly enough, Simon Frith (2004), a major contributor to this literature on British youth subculture, recently observed that what is being called 'postsubcultural theory' (Bennett and Kahn-Harris, 2004; Muggleton and Weinzierl, 2003) does not focus on youth at all. So, despite all the controversy, it appears that the usage of the concept of 'subculture' may have come full circle and is now being used in the same two ways Yinger noted were common in 1960, in a more general sense but sometimes also in what is now identified as a Birmingham School approach incorporating a notion of resistance or conflict.

Albeit the approach to subculture inspired by the Birmingham School seems to have run its course, now much more is known about youth subculture, not just in Britain, but globally (e.g., Baron, 1989; Jasper, 2004; Johnston and Snow, 1998; Maira, 1999; Mitchell, 2003; Platek, 1990). Furthermore, the debates over the validity and utility of the concept of subculture have led to the application and sometimes development of related concepts that have shed light on other aspects of social groups that could have been studied using a subcultural theoretical lens. So, although as Muggleton and Weinzierl (2003: p. 5) observe, "a new, dominant paradigm has yet to develop," a plethora of concepts have been proposed to replace or supplement the old one. Although most of the critiques of the concept of subculture have been in response to attempts to apply it to study a specific type of social group that has characteristics not revealed by its application, the tendency of most authors seems to be to try to propose a definition of subculture or an alternative concept that will be consistently useful to apply across social groups. Here we propose a different approach, which is to embrace the use of a variety of concepts, including subculture, to study the component social groupings of a larger one and thereby to increase what is known about them.

To elaborate on this proposal, it is useful to understand subculture and its related concepts as what Vaihinger (1925) called 'neglective fictions.' Although fictions are devoid of reality, they are not devoid of utility. According to Vaihinger, 'fictions' have been used to advance scientific understanding of phenomena, much like hypothesis testing has. We are suggesting here that concepts such as 'subculture,' 'contraculture,' and others to be discussed in this article be applied to social groupings, much as Adam Smith (1776/1976) wrote about human behavior 'as if' it were all egoistic. He deliberately substituted a fraction of reality, what Vaihinger called a 'neglective fiction,' for the total range of possible explanations and facts. Without this substitution, Smith would have been unable to construct an ordered interpretation of the political economy. Similarly, without using neglective fictions such as subculture, contraculture, culture of resistance, lifestyle, tribe, scene, subworld, or subsociety as lenses, the understanding of the role of these groupings in shaping identity and society would not be as great. We are suggesting that researchers could use and have used various concepts related to subculture either independently or in sequence as lenses to study subgroups of a larger culture or society as Simmel (1986/1907) would apply various forms (i.e., various neglective fictions) to the same content (Adams, 2010; Kaern, 1983). Through this process, which is already ongoing though the researchers using this approach might not associate it with Vaihinger's scientific fictions, not only will we learn more about the social groupings under scrutiny, we will also reach greater understanding of the utility and patterns of relevance of the theoretical concepts themselves.

In keeping with this perspective on subculture and related concepts as neglective fictions, many of the related concepts just mentioned have been developed in response to attempts to understand specific social groupings by first using subculture as a lens and finding it lacking for some theoretical or substantive reason. For example, Crosset and Beal (1997) propose the use of the concept 'subworld' in addition to the concept 'subculture.' Building on Unruh's (1983) definition of social worlds "as large and highly permeable, amorphous and spatially transcendent forms of social organization made up of people sharing common interests and sharing common channels of communication," they note that "[t]he concept of 'social world' pushes the researchers' gaze in a slightly different direction than does 'subculture'" (p. 81). Unlike analyzing sports as subculture, analyzing it as a social world allows the discovery of subworlds within social worlds, and at least unlike analyzing sports from a CCCS perspective, it "frees the researcher from looking for signs of cultural resistance in every sporting practice." Similarly, although the concept of 'scene' is not a new one (Irwin, 1977) and originally described expressive, voluntary, public gatherings that take place in urban locations, Straw (1999: p. 373) and others have recently introduced the term scene in part to replace older conceptions of music communities as having relatively permanent membership focused on specific musical idioms. Straw's reconceptualization of 'scene' casts it as a space in which a range of musical activities coexist and cross-fertilization and change take place. Miles (2000) provided a third example of a concept introduced in order to understand a specific phenomenon when he argued that the application of the term 'subculture' to heavy drug users makes sense, but suggested 'lifestyle' as a more useful term when researching people whose drug use is intermittent.

Rather than suggesting 'subculture' be replaced with other concepts because of the inadequacy of subculture to highlight the important features of a specific social grouping, sometimes theorists have recommended it be replaced by other concepts in response to widespread social changes such as globalization and multiculturalism. Like Miles (2000), Chaney (2004) also suggests the use of the term 'lifestyle' might be more useful in the contemporary context but for very different reasons. He argued that the idea of a multicultural world has rendered the distinction between dominant and subcultural norms moot and therefore the notion of a dominant culture as a context for subcultures archaic. Furthermore, he (Chaney, 2004) argued that the widespread availability of a greater variety of cultural styles and identities suggests the notion of subculture with that of lifestyles as the basis for the negotiation of identity, community, affiliation, and difference. Implicitly he argues that subcultures no longer exist.

More recently, the definition of subculture is being scrutinized for its usefulness in the context of improved communications and transportation technology (Bennett, 2004). The Chicago School studies of subcultures such as taxi dancers (Cressey, 1932) and gangs (Thrasher, 1927) were situated in local contexts and the need for close proximity and face-to-face interaction were assumed to provide a foundation for their development, persistence, and stability. Although it is the advent of the Internet that has led subculture scholars to challenge these assumptions, other earlier improvements in communications and transportation technology such as the postal system, telegraph, telephone, steam ships, locomotives, and automobile began changing the way subcultures developed and persisted much earlier (Adams, 1998). Nonetheless, the Birmingham School's examination of punks in the United Kingdom in the 1970s continued the Chicago tradition of focusing on subcultures in the local context, and much of the work accomplished by scholars elsewhere but working within these traditions often did the same.

In this regard, the subculture literature has lagged behind the community literature in which the discussion of non-territorial communities had already begun in the 1960s (Webber, 1963; Effrat, 1974) and has continued since (Adams, 1998; Wellman, 1999). As a result, scholars who have studied migrating groups or intermittently territorial groups such as the New Age Travellers (Frediani, 1998), some music fans (Gardner, 2004), or National Association for Stock Car Auto Racing spectators (Wright, 2002) have sometimes implicitly if not explicitly used 'community' as a conceptual lens rather than 'subculture.' For example, in her study of Deadheads, the fans of the Unites States rock group the Grateful Dead, Adams originally intended to use 'subculture' as a conceptual lens (Adams, 1990), but subsequently shifted to using the concept of 'community' for this purpose in part because it allowed a focus on the development and continuity of identity and solidarity across time and space (Adams et al., 2014). Although the members of such communities do not share a permanent territory, like members of local subcultures and traditional communities, they are bound by affect, customs, and common interests (Nels, A. and Council of Social Agencies of Chicago,

1923; Tönnies, 1963/1887). Also like local subcultures and traditional communities, these intermittently territorial communities sometimes serve the functions of production, distribution, and consumption; socialization; social control; social participation; and mutual support (Humphreys, 1970; Warren, 1978).

In contrast to Chaney's (2004) position that the notion of subculture is archaic in a multicultural world, it could be argued that with the advent of the Internet and the related development of virtual media of various forms, it is even easier for subcultures to transcend space and time and for true global subcultures to exist. As one celebrates the 25th anniversary of the World Wide Web, it seems particularly appropriate to reflect on its impact on culture. As early as 1994, Rheingold discussed the 'virtual community' and connectivity within it. Shortly thereafter, Healy (1997) described it as a 'loose collection' or 'ecosystem' of subcultures (p. 65). Subsequently, scholars in both the community (Smith and Kolluck, 1999) and subculture traditions (Bennett, 1999) began considering how the Internet challenged the relevance of concepts developed in an earlier time period. The literature on migrating or intermittently territorial communities is somewhat useful here, because like the literature on online subcultures, it does not assume permanent shared territory and once the Internet developed these communities also manifested themselves online. Although as Bennett (2004) astutely observed, subcultural studies often overlook the continuities between online and offline interactions, not all virtual communities manifest themselves locally. The development of the Internet has thus exacerbated concerns of postmodernists such as unstable identities (Lash and Urry, 1987, 1994) and the lack of emotional and moral depth of communities based solely on common interests (Bauman, 1992).

Taken together, these concerns beg the current question of whether this technology detracts from the development of subcultures that provide the context for stable identities and feelings of solidarity with a subculture of like-minded people or leads to shifting identities and weak commitments to multiple subcultures. This question is particularly salient in light of the emergence of 'one device' portable technology and the ability of people to remain 'plugged in' constantly and to manage activity in multiple subcultures or communities at one time. On the one hand, simultaneous ties to multiple communities can be hypothesized to weaken the individual connection to a subculture, thereby making it more likely that individual identities will shift over time and weaken subcultural solidarity. On the other hand, even before the advent to of the Internet, Fine and Kleinman (1979: p. 12) noted that multiple group memberships promote cultural diffusion and the spread of subcultures, and more recently Thornton (1996) has argued that media, including the Internet, are integral to the formation of subcultures, playing a significant role in both their origin as well as prolonging their life cycle. McArthur's study of the virtual subculture of 'geeks' supports Thornton's observation as it would have been very difficult for his participants to meet in person as they were from many nations including The Philippines, England, Argentina, and Czech Republic (McArthur, 2009). Future scholarship will hopefully reveal the waxing or waning of the significance of subcultures in a global society.

Methodology

Subculture researchers have relied mainly on ethnographic methods, as qualitative approaches afford insight into valuable details difficult to capture with a broader lens. Due to previous conceptions of subculture as local and therefore convenient (both in the traditions of the Chicago and Birmingham Schools) and the tendency of researchers to study deviant subcultures that are difficult to enter, much of the research on subcultures has specifically involved participant observation. Nonetheless, as many researchers, including Fine and Kleinman (1979), acknowledged years ago, the narrowness of such methods embodies their own limitations. For example, a case study of one gang could not claim representation of all gangs in a given population or yield any definite findings regarding the degree of interrelatedness between them.

Some subculture researchers have thus instead conducted surveys of samples of general populations (e.g., King, 2007; Latysheva, 2011), but this method can be ineffective, especially if the interviewer is not identified with the subculture or when the interviewer's values differ from the subculture's. Returning to the aforementioned limitations of a finer lens, "while case studies provide valuable information about the culture, it is unclear to what extent they provide evidence of the culture as a population segment" (Fine and Kleinman, 1979: p. 4). Yet, the broader study of general populations also yields difficulty, particularly in identifying subcultural groups (King, 2007). Given that in order to demonstrate a subculture's existence, a subpopulation's relative agreement on a set of attitudes, behaviors, or values must be identified, the researcher must necessarily show that communication occurs within that subpopulation and that its members identify as a group. For this reason, even in the challenging case of studying migrating or intermittently territorial subcultures, researchers examining them have tended to supplement any survey or documentary research with their observations (e.g., Hunt, 2008, 2010; Riley, 1988).

The globalization of culture and the introduction of the Internet and related technologies have not only challenged theoretical conceptions of subculture, but have also led to changes in how they are studied. As exemplified by McArthur (2009) in his study of 'geeks,' the Internet allows new formats for data to be gathered on subcultures, at the same time that it allows for new forms of expressing subcultural identity, as well as influencing those identities themselves. The future of subculture analysis may benefit from the accessibility of information and even the resurfacing of past information and data previously obscured by data security policies (although individuals participating in subcultures through different mediums in the past may never have realized that information would one day be made available electronically and via search engines). The criticism that studies are focused on subcultures at one point in time can now be addressed by expanding the search backward and more broadly to include an ever-increasing amount of information available online. The Internet also makes it possible to study distant subcultures remotely. Finally, videos and multimedia files produced by other researchers are shared in the advent of a very open attitude toward information sharing.

Although the advent of the Internet facilitates research on subcultures, it also complicates it. Despite the growth of the Internet, it is not equally accessible to all populations. The 'digital divide' represents the absence or limitation of access to the Internet for certain people or groups based on affordability, knowledge, or motivation. Furthermore, even in the hypothetical scenario that all potentially desired participants would have similar access to and know-how regarding these technological means, self-selection would remain an issue.

Nonetheless, the increased availability of information will certainly aid in research on subcultures that exist in a variety of modes and will address some of the previously articulated, but nonetheless still valid, challenges of qualitative research identified by Fine and Kleinman (1979): the Internet makes it possible to discover linkages among groups, track the transmission and forms of information and exchanges of communication, and identify kinds of information that is transmitted. Furthermore, given the progression of technology to allow for more remote and anonymous participation in a subculture, many studies themselves may in turn become focused purely on online cultures (King, 2007). While ethnography remains an important method for studying subculture, the existence of the Internet may lead to the realization of a new form of interdisciplinary research, combining ethnography with methods such as textual analysis (Pollex, 1997), an approach some have called 'postmodern ethnography' (Tyler, 1986). Such a new method would have to be focused on mining data and organizing it in such a way that large numbers of disparate pieces can be integrated and interpreted in meaningful ways. The Internet spreads information quickly and retains it forever, so future subcultural analysts will need to develop methods for sampling this vast array of information and deciding how valid it is. As the information age continues to unfold, the challenges and benefits the Internet poses to theorists and researchers will no doubt lead to substantial changes in how subculture is understood and studied.

Subjective Wellbeing and Culture

Sim Jing Han and Sharon Koh, Singapore Management University, Singapore, Singapore
Christie Napa Scollon, School of Social Sciences, Singapore Management University, Singapore, Singapore

Abstract

Subjective well-being (SWB) is what most people refer to as happiness. It is people's subjective sense that life is going well. Many factors influence SWB, and culture is of course an important one. The present article describes the cultural differences in SWB, beginning with the desirability of happiness around the world. Next, the authors discuss the major cultural differences in SWB, for example, which regions and cultures are happiest. Next, the article reviews the literature that has sought to explain the cause of these differences. Finally, the article concludes with a view toward future research in culture and SWB.

What does it mean to be happy? What is a good life? Most of us have thought about these questions at some point in our lives. Researchers studying subjective well-being (SWB), however, seek to empirically study happiness through the use of scientific methods like surveys and laboratory experiments to investigate, for example, who is happy and what are the societal conditions that contribute to happiness.

Within this field, the impact of culture on SWB has been of interest to researchers. At the most basic level, one of the key questions that researchers try to understand is whether happiness is a universal value that is important to people around the world. Next, if some cultures are happier than others, we would want to know why this occurs. After all, if some cultures are doing things that promote happiness, perhaps less happy nations could learn a thing or two from the happy ones. In addition, researchers constantly face the challenge of different cultural conceptions of happiness and how to make meaningful comparisons in light of these differences. In this article, we review the current literature in the study of SWB among cultures and discuss the factors that contribute to these differences.

Definitions

What Is Subjective Well-Being?

SWB is what most people recognize as happiness. Among researchers, SWB broadly refers to people's subjective evaluations of their lives. It is people's subjective sense that life is going well. The specific components are typically measured as the frequency of pleasant over unpleasant emotions as well as a cognitive evaluation of one's life as a whole (i.e., life satisfaction) (Diener, 1984). Although these components are highly correlated – that is, someone with high SWB typically experiences lots of pleasant emotions, few unpleasant ones, and has high life satisfaction – the components have been demonstrated to be empirically separate as well. Importantly, because of the subjective nature of SWB, most researchers measure SWB simply by asking people how they feel about their lives. This straightforward approach has been shown to have strong validity and is conceptually meaningful. Of course, SWB researchers do not argue that objective indicators of a life are not important, rather that SWB is about the subjective evaluation of one's life and therefore people are the best sources of information about their own happiness.

What Is Culture?

When thinking about culture, we typically consider various aspects of societies like religion, food, and language. Psychologists, however, understand culture to be something deeper and define culture as an evolved collection of practices and beliefs that people share and transmit between generations in order to allow them to coordinate their actions and satisfy their needs (Chiu et al., 2010). Simply put, culture is a shared understanding of how we go about living together in groups. Researchers studying culture commonly examine how people understand themselves, their values, as well as their environment.

Broadly speaking, the ideas of individualism and collectivism provide us with a useful way to think about different cultures. In individualist cultures, the uniqueness of individuals and their choices and achievements are the focus of a person's identity (Hofstede, 1980; Triandis, 1989). In collectivist cultures, group memberships shape a person's identity and group goals are more important than personal desires (Triandis, 1989). For example, individualists are more likely to finish the sentence 'I am …' with personal traits (e.g., 'I am a boy' or 'I am very intelligent'). Collectivists, on the other hand, tend to finish the same sentence with social roles or group memberships (e.g., 'I am a son' or 'I am a student') (Diener and Diener, 2008). There are variations in the classification of cultures within the individualistic–collectivistic spectrum. As a general guideline, most Western societies like the United States and Australia are characterized as individualistic while Eastern Asian societies like Japan and South Korea are collectivistic cultures.

Differences in SWB around the World

The Desirability of Happiness across Cultures

Happiness appears to be a universal value for people around the world. Diener (2000) asked college students from 42 different countries about the importance of happiness, love, going to heaven, and being rich. Happiness emerged as the top

value in every country studied, even edging out values such as eternal salvation and wealth. Happiness scored well above the midpoint in every single country, typically around a 7 or an 8 on a 10-point scale where 10 equaled 'extremely important.' The lowest rating given to happiness was 5.03 in Bulgaria. Although there were differences among countries in the importance assigned to the various values, in no society sampled did happiness emerge as less important than wealth.

The Experience of Happiness across Cultures

Though most people desire to be happy, actual scores of happiness vary widely across cultures. There are now several comprehensive world-wide surveys that provide an annual rank order of nations in terms of the happiness of their citizens. For example, Gallup recently conducted a survey of happiness that involved over 100 000 respondents in over 100 countries, with representative samples in each country. In addition, the United Nations also releases an annual publication, the World Happiness Report that incorporates data from over 150 countries. Similar to the study by Diener (2000), the World Happiness Report uses a variant of the satisfaction with life scale, asking participants to rate their overall satisfaction with life on a 10-point scale where 10 equaled 'completely satisfied.' Based on data collected from 2010 to 2012, this report ranked Denmark, Norway, and Switzerland as the most happy in the world, while Central African Republic, Benin, and Togo ranked lowest (Helliwell et al., 2013).

While it is silly to debate whether the number one spot belongs to Denmark or to Luxembourg, and whether Singapore is 30th or 33rd, there are clear and consistent regional differences in reports of SWB. In general, countries in North America and Australia/New Zealand are quite happy, as are countries in Western Europe and Latin America. The African nations are almost always overrepresented in the bottom of the rankings, while the Middle Eastern states are also not very happy. Asia is not miserable, but is also not nearly as happy as the Western societies. While the unhappiness of the African states makes sense in light of their economic conditions, the happiness of Asian countries is surprisingly low, given their gross domestic product (GDP), and this continues to puzzle scientists interested in culture and SWB (Diener et al., 1995). Interestingly, Rice and Steele (2004) examined Americans who varied in ancestry and found that people's SWB levels were more strongly related to that of their ancestors than that of their current neighbors. In other words, a Chinese American is more like the Chinese in China in reports of SWB than an Irish American!

Why Do Cultures Differ in SWB?

Gross Domestic Product

Part of the differences in SWB across countries can be explained by the differences in their GDP. Across multiple studies, the wealth of nations is one of the strongest and most reliable predictors of national levels of life satisfaction (Diener and Suh, 1999). In other words, countries with the highest SWB levels also tend to be wealthy (e.g., Switzerland and Denmark), while countries with the lowest SWB levels tend to be the underdeveloped nations (e.g., Bulgaria and Tanzania).

However, while GDP is a predictor of SWB across countries, Myers (2000) and Diener and Oishi (2000) have also found that mean happiness levels have not been increasing dramatically over time, although income has. Known as the 'Easterlin Paradox,' this is likely due to the rising expectations associated with the rise in income, where people now have higher economic desires that negate the gains in their happiness levels.

Although countries with higher GDP experience higher SWB, the association between GDP and SWB is not perfectly linear and there are some countries that report unexpectedly higher or lower life satisfaction levels. For example, the high wealth of the four Asian tigers, Hong Kong, Singapore, South Korea, and Taiwan, should predict relatively high levels of SWB in those countries. Yet in many of the happiness surveys conducted worldwide, citizens from these four countries typically do not report experiencing high levels of SWB. In fact, the recent Gallup World survey reported that Singaporeans were the least likely in the world to report experiencing emotions of any kind on a daily basis (Clifton, 2012). Meanwhile, the low wealth of the Latin American countries should predict lower SWB than is observed, but countries like Chile and Brazil consistently report relatively high levels of SWB (Helliwell et al., 2013), suggesting that GDP alone is insufficient in providing us with a complete explanation of the cultural differences in SWB among countries.

Individualism-Collectivism

Across multiple studies, researchers have found that individualism correlates with higher SWB (Diener et al., 1995), indicating that individualistic cultures experience happiness more frequently and more intensely than collectivistic cultures (Eid and Diener, 2001). Countries high in individualism, like the United States and Canada, tend to report higher SWB levels compared to collectivistic cultures like China and Japan. At the individual level, individualists, compared to collectivists, also tend to report higher happiness levels, and this correlation holds even if the individualist is in a collectivistic society like Asia. For example, an American living in Japan is more likely to report higher happiness levels compared to a Japanese person living in the same country (Diener, 2000). It may be that collectivist values are at times incompatible with personal happiness, for example, when an individual chooses to sacrifice his/her own personal happiness in order to maintain group harmony.

Although the relationship between individualism and happiness is fairly strong, there are however exceptions to this trend where individualism correlated with higher SWB. Across multiple studies, researchers have found that Asia and Latin America are similar in their levels of collectivism. Thus, it follows that they should report similar happiness levels, and yet Latin Americans have consistently outscored Asians in well-being surveys, including the recent World Happiness Report 2013, puzzling researchers.

Norms Regarding Happiness and Other Positive Emotions

Diener et al. (2000) examined norms toward happiness by asking participants in 40 different societies to rate the ideal level of life satisfaction an ideal person would experience.

Interestingly, Diener found a good deal of variation in responses to this question around the world. To the surprise of Americans, not everybody said that the highest levels of happiness were the most ideal. Although all respondents agreed that the ideal level of happiness was above neutral, some respondents were much closer to neutral while others were much closer to the top of the scale. Ideal levels of SWB also correlated with actual levels of SWB and corresponded to a nation's general positivity bias as well. Overall, Asian countries displayed little positivity bias and lower ideal SWB scores, while Latin American countries displayed the most positivity bias and the highest ideal SWB scores. North American and European countries were in between.

Why is there less of an inclination toward positivity in Asian cultures? And why do Asians report lower levels of ideal SWB than say Latin Americans and North Americans? The answer may lie in the value that negative emotions have in Asian societies. Feelings such as guilt, although unquestionably unpleasant, can serve to enhance group harmony. On the other hand, although pride may feel good, pride about the individual's goal accomplishments may set the individual apart from group members. Eid and Diener (2000) found that respondents in North America and Australia overwhelmingly preferred positive emotions and devalued negative ones, whereas in Asia, respondents were more balanced in their views, noting that even unpleasant feelings have value.

Different Definitions of Happiness

Societies like the United States recognize happiness as a high-arousal positive state, where happiness is an upbeat and energetic emotion, featuring intense emotions like excitement and exhilaration while cultures like Japan tend to define happiness as a low-arousal positive state, which involves being calm, relaxed, and in a peaceful state of mind, with everything in harmony (Tsai et al., 2006). Consistent with self-reports of these emotional states, Tsai et al. (2007) examined best-selling children storybooks in the United States and Taiwan and found that American storybooks had more excited expressions, wider and open-mouth smiles, and more arousing activities. On the other hand, happiness in Taiwanese storybooks was often depicted with closed-mouth smiles and closed eyes.

Different Strategies in Pursuing Happiness

Cultures could also differ in happiness due to the strategies they use to pursue happiness. Individualistic cultures adopt a promotion-focused orientation toward achieving a goal, focusing more strongly on information that is relevant to attaining their desires and they also place more emphasis on positive than on negative information regarding themselves (Lee et al., 2000). Thus, individualists will actively seek out situations that could maximize their well-being. For example, they may seek out happiness-inducing activities like dinner with friends or exciting activities like bungee jumping, allowing them to experience more happiness.

A collectivistic culture, however, adopts a prevention-focused orientation toward goal achievement, and more attention is placed on information that prevents them from violating social norms and also emphasizes negative information about themselves (Lee et al., 2000). Thus collectivists might actively avoid situations that could negatively impact their happiness levels as they might have the mindset that "I will achieve happiness if nothing bad happen to me throughout the day." Therefore, they would try to avoid conflict with people in an attempt to protect themselves from unhappiness.

Cultural Differences in Materialism

Materialism, which is the tendency to believe that consumer goods and services provide the greatest source of satisfaction in life (Belk, 1985), could also explain some of the cultural differences in happiness. Research on materialism and happiness has consistently shown that materialistic people are less happy. To the extent that cultures differ in their focus on materialism, we might expect there to be differences in SWB.

Wirtz and Scollon (2012) and others have shown that, indeed, materialism differs among cultures. In their study, they found that Asians and Americans both strongly valued happiness and meaning in life when judging life quality. However, Americans perceived life desirability to be less dependent on material success than on the presence of happiness and meaning in life. Asians, on the other hand, were more likely to view a life characterized by high material success as more favorable, suggesting that materialism may be more congruent in Asian societies. Wirtz and Scollon (2012) further demonstrated that priming a collectivist perspective enhanced the importance of wealth in judgments of a good life.

Measurement

Are there cultural differences in response styles that could account for the cultural differences in SWB? One argument that has been made is that Asians tend to avoid providing extreme values in a survey, preferring to use the middle of scales more. However, Diener et al. (1995) tested this hypothesis and found little support for it, as they found that compared to Americans, Asians reported a greater range of moods, indicating that Asians were not adverse to reporting extreme moods.

Still, there is still good evidence that how SWB is measured does contribute to cultural differences in SWB in several systematic ways (Scollon et al., 2011). First, cultural differences are often more pronounced with positive emotions. For example, Scollon et al. (2004) compared momentary reports of positive and negative effects provided by European Americans, Asian Americans, Hispanic Americans, Japanese, and Indian students and found greater cross-cultural differences in positive compared to negative emotions. Why are positive emotions more susceptible to cultural influences than negative emotions? Researchers believe that positive emotions may be subjected to greater social learning influences than negative emotions that have stronger genetic and biological constraints. Tellegen et al. (1988), for example, found that there were stronger genetic effects for negative emotions between twins. For positive emotions, common environmental experiences such as parenting and household environment had a stronger impact. This suggests that the learning of positive emotions might require greater social interactions and reinforcement. Considering that positive emotions are valued differently

amongst different cultures, it is likely that this reinforcement of positive emotions would also differ across cultures.

Second, larger cultural differences in SWB have also been found as the time frame of measurement is increased. For example, when considering how satisfied you were with your life in general over the past year, compared to your life satisfaction yesterday or in the past hour, researchers tend to find greater cultural differences when participants consider their satisfaction over the past year. Furthermore, Oishi (2002) found that there were differences in how cultural groups remember their experiences because while Asian Americans and European Americans did not differ in their daily self-report of emotions, European Americans, compared to Asian Americans, recalled a higher degree of well-being.

Cultural differences are larger for such retrospective reports because such reports are not exact duplicates or summations of momentary experience. Instead, these memories are reconstructed (Robinson and Clore, 2002). When evaluating their experiences, people tend to first consider their event-specific information, piecing together every detail that they can remember about the event, before concluding with an overall judgment of their experience. For example, when asked to recount whether lunch was an enjoyable experience, you may seek to systematically recollect the various details of lunch, the food you ate, and the company you were with. Once you have established all the facts, you then cognitively appraise all these details to conclude whether lunch was enjoyable or not.

However, as the time frame increases, it becomes increasingly hard for people to integrate all aspects of the experience together. Imagine trying to recount how pleasant your overall lunch experience was over the past year. It is almost impossible for us to remember all the lunches we had over the past month, much less a year. People then begin to use their nonevent-specific information, which includes their cultural values and beliefs, to fill in these memory gaps. Using such nonevent-specific information could thus result in differences to their retrospective evaluations as cultures hold different views about the desirability of particular emotions such as happiness (Scollon et al., 2011).

Future Research and Conclusions

While research in SWB and culture has explained some of the discrepancies between countries, many questions still remain and new findings warrant further investigation. Although there are some impressive worldwide data sets, most of the studies in the field compare two countries on a limited set of SWB variables at a single point in time. More comprehensive and longitudinal studies, and more importantly, interdisciplinary approaches are sorely needed. Although psychologists and economists have made important discoveries in SWB thus far, more progress will be made at the intersection of these fields and others such as policy studies, genetics, sociology, and environmental studies. As policy makers grow increasingly aware and interested in national indicators of SWB, the data will become available in time to examine the impact of social policies on SWB. Cultural explanations for cultural differences will need to be further unpacked to examine the source and development of cultural beliefs; thus, the field could benefit from collaborations with anthropologists and ethnographers as well as those who study consumer behavior. The possibilities are limitless.

One example of the exciting developments in interdisciplinary approaches to understanding cultural differences in SWB for this area combines behavioral genetics, epidemiology, and well-being research. In the first study of its kind, De Neve (2011) found support for a direct link from genes to happiness. Specifically, people with a certain variant (long alleles) of the serotonin transporter gene (5HTTLPR) tend to report higher satisfaction. Meanwhile, people with the short alleles of 5HTTLPR tend to report lower life satisfaction. Interestingly, the distribution of the polymorphisms of 5HTTLPR appears not to be the same across different ethnic groups and different regions of the world, which means that cross-cultural comparisons on SWB have been confounded with differences in genetic variation. Compared to North American and European countries, Asian countries have more of the short alleles represented in their populations, which could possibly account for the lower levels of SWB in those parts of the world as suggested by Proto and Oswald (2013) and Scollon et al. (2011). Clearly, however, more research is needed.

In summary, people around the world want to be happy. Yet, scores of happiness vary widely across cultures. Past research on culture and SWB has revealed that cultural differences in SWB can be explained in part by societal wealth, individualism, materialism, cultural norms regarding positive emotions, and possibly genetic differences. Future research on culture and SWB remains an exciting area with opportunities for interdisciplinary explorations.

Abstract

Although people have been intrigued by happiness for centuries, subjective well-being became a thriving topic of scientific inquiry only relatively recently, with the creation of valid and reliable well-being measures. Growing evidence suggests that happiness is associated with success in multiple domains, such as relationships, work, and health. However, objective life circumstances do not impact well-being as much as people believe, in part because of hedonic adaptation – one of the biggest obstacles in the pursuit of happiness. Fortunately, researchers have found that positive activities, like expressing gratitude or doing acts of kindness, can have a significant impact on well-being.

Historical Background

Although people have contemplated what makes life meaningful and worthwhile for millennia (Keyes, 2006), happiness did not become a subject of scientific inquiry until relatively recently. Prior to the 1970s, researchers focused on topics such as obedience, conformity, and aggression in an attempt to understand the devastation of World War II. As the world began to recover from the effects of wartime, psychological scientists became interested in monitoring and improving social change. This interest led to a newfound appreciation of the individual, as many believed that the key to understanding social change could be found in the study of the individual's attitudes, expectations, and values. The outcome was an increased focus on the importance of an individual's sense of meaning and views on life. Measures of quality of life were developed to monitor social change and influence social policy, and subjective well-being began to emerge as a field of scientific study.

Definition and Measurement

Today, researchers generally agree that subjective well-being is a broad construct that refers to evaluations of the quality of one's life and includes both an affective and a cognitive component (Diener et al., 1999). The affective component refers to the frequency of experienced emotions, such that individuals with high levels of subjective well-being report high levels of positive affect (i.e., many pleasant emotions) and low levels of negative affect (i.e., few unpleasant emotions). The cognitive component comprises overall life satisfaction, as well as a person's evaluations of multiple life domains, such as work, health, and relationships. Importantly, because respondents determine whether their own lives are worthwhile and meaningful, the concept of well-being is inherently subjective and democratic. Hence, researchers commonly use the term subjective well-being (SWB), as well as happiness, and these terms are used synonymously throughout this article.

Since the field's beginnings, researchers have relied almost exclusively on self-report measures of happiness. As such, multiple self-report scales of well-being are now widely used. Investigators initially developed simple measures prompting participants to make general evaluations about their lives (Krueger and Schkade, 2008). Specifically, participants are asked a single general question about their overall happiness or satisfaction with life. Such global measures are still most popular, having been incorporated into large-scale surveys, such as the Gallup World Poll and World Values Survey. Indeed, global scales have been invaluable for gaining insight on well-being around the world and have allowed for comparisons in happiness and satisfaction in large representative samples across cultures and across decades (Helliwell et al., 2013).

Although single-item measures of well-being are simple and easy to administer, it is difficult to capture how happy a person is with a single question. To address this limitation, global, multiitem measures of well-being were created and validated. Today, a number of validated self-report measures of happiness, affect, and life satisfaction are in common usage, including the Satisfaction with Life Scale (Diener et al., 1985), Positive and Negative Affect Scale (Watson et al., 1988), and Subjective Happiness Scale (Lyubomirsky and Lepper, 1999).

Other measures of well-being are intended to capture its affective component. For example, with the Experience Sampling Method, participants are prompted to report their current emotions and thoughts at random intervals throughout the day (see Csikszentmihalyi and Larson, 1987). This method, however, can be difficult to administer because it requires a large time commitment from participants. The Day Reconstruction Method (DRM) is another popular approach to measuring well-being. Participants are asked to consider the preceding day, break it up by time into different episodes, describe each episode, and report their well-being during that part of the day (Kahneman et al., 2004). Given that people in a happy mood are relatively more likely to recall positive information (Schwarz and Clore, 2003), with their current mood coloring their interpretations of the past, memory biases may be minimized with the DRM because participants are pressed to recall what they were feeling during a specific time (e.g., while commuting to work) after describing the episodes of the previous day.

Self-report measures of well-being have their limitations. Fortunately, researchers have found that self-report ratings of

happiness are reliable over time (Diener, 1994), correlate with theoretically relevant constructs (Larsen et al., 1985), and converge with non-self-report measures, such as reports of family and friends (Sandvik et al., 1993). With the creation of valid and reliable measures of well-being, research on happiness has grown rapidly and developed into a thriving new field. The ability to assess well-being has opened the door for researchers to investigate numerous previously elusive questions, such as what are the determinants and correlates of happiness, what are its benefits or costs, and, perhaps most important, whether and how happiness can be increased.

Benefits of Subjective Well-Being

Happiness involves much more than simply an emotion that feels good. The experience of positive affect allows happy people to build social, intellectual, physical, and psychological resources (Fredrickson, 2001). It may also signal to the individual that everything is going well, thus allowing him or her to be more creative, productive, approach oriented, and social. Accordingly, happiness leads to a variety of beneficial outcomes via an increase in behaviors that offer individuals the opportunity to achieve success in multiple domains (Lyubomirsky et al., 2005a). For example, happy individuals have a relatively greater tendency to seek out relationships, exhibit helping behavior, be productive at work, and cope successfully with life changes. As such, happiness has been found to benefit one's interpersonal relationships, work life, and health.

Social Relationships

Happy individuals tend to have successful social relationships. For example, happier people are relatively more likely to seek out both formal and informal social activities (Okun et al., 1984), and, thus, engage in frequent social interactions. This high level of social engagement may allow them to build stronger, deeper bonds with others. It is therefore not surprising that happy people tend to report having more friends and social support than their less happy peers (Baldassare et al., 1984; Mishra, 1992). Happier individuals are also relatively more likely to get married and to report higher marital satisfaction (Harker and Keltner, 2001; Headey and Veenhoven, 1989; Marks and Fleming, 1999). In turn, having a solid social network may make people relatively better equipped to handle negative life events. Belonging to a social group promotes better mental and physical health, granting people the resources to manage life changes and cope with illnesses (Jetten et al., 2012).

Work

A large portion of an individual's time and energy is spent at work or pursuing work-related activities. Indeed, work is a vital source of income and self-esteem for many people. Importantly, happier individuals are relatively more likely to have successful work lives and tend to be more satisfied with their jobs. For example, happy people are more likely to obtain a job, have high job satisfaction, and feel financially independent at an young age than their less happy counterparts (Roberts et al., 2003). Furthermore, supervisors tend to rate happy workers relatively higher on productivity, work quality, creativity, and dependability (Cropanzano and Wright, 1999). Happiness has also been found to predict increases in income and lower rates of unemployment over time (Graham et al., 2004; Marks and Fleming, 1999).

Physical Health

Subjective well-being is associated with a number of positive health outcomes. For example, happy people report having better health, missing less work due to illness, and making fewer visits to the hospital than less happy people (Graham et al., 2004). One possible reason for superior physical health may be the association between happiness and strong immune functioning. For example, one study found that healthy individuals with a positive emotional style were relatively less likely to get a cold after exposure to a rhinovirus (Cohen et al., 2003). Notably, happiness is even related to longevity (Chida and Steptoe, 2008). Happy people are relatively less likely to experience be diagnosed with cardiovascular disease (Davidson et al., 2010) or suffer fatal accidents (Kirkcaldy and Furnham, 2000), and they are more likely to survive illnesses like HIV (Ickovics et al., 2006).

The Role of Genetics in Well-Being

Researchers have found that well-being is moderately stable (Headey and Wearing, 1989; Lykken and Tellegen, 1996), such that, for example, happier individuals tend to remain consistently happy over time. One of the reasons for this stability is that people show shifts in well-being after positive and negative events, but, as described in greater detail below, gradually return to their previous happiness levels over time. A growing literature has accumulated evidence that this baseline level of happiness is in part influenced by genetics (Bartels and Boomsma, 2009; Lykken and Tellegen, 1996; Rietveld et al., 2013). The genetic component of well-being is investigated by comparing the correlations between the reported SWB of monozygotic (identical) twins to that of dizygotic (fraternal) twins. Identical twins have been found to report more similar levels of happiness than fraternal twins, even if they were raised in different households (Bartels and Boomsma, 2009; Lykken and Tellegen, 1996). For example, one study found that up to 80% of the stable component of happiness is heritable, with nonshared environmental factors accounting for the remaining variance (Lykken and Tellegen, 1996). Although studies have found varying heritability coefficients (ranging from 0.25 to 0.55), the overwhelming conclusion of this research is that happiness has a large genetic component.

Related work suggests that personality may underlie the genetic influence on happiness. Subjective well-being is highly positively correlated with extraversion and negatively correlated with neuroticism (Costa and McCrae, 1980; DeNeve, 1999; Furnham and Brewin, 1990; Hayes and Joseph, 2003), with mixed evidence on its relationship with other personality factors, such as agreeableness and conscientiousness. Because, much like SWB, personality has a genetic component,

a relationship between the genetic influence on personality and the genetics of happiness may exist. One study found evidence to suggest that the genetic influence on extraversion, neuroticism, and conscientiousness entirely explains the heritability of SWB (Weiss et al., 2008).

Correlates of Subjective Well-Being

The nonheritable correlates of subjective well-being can be broadly divided into two categories: objective environmental circumstances (such as income or marital status) and intentional cognitions and behaviors (such as prosocial behavior; Lyubomirsky, 2001). Laypeople are often surprised to learn that objective circumstances or demographic variables are weaker predictors of well-being than volitional behaviors. For example, men and women in nations across the world report being happy and satisfied with their lives with equal frequency (Inglehart, 1990), although the two sexes tend to be unhappy in different ways (Myers, 2000). Furthermore, the well-being gains or losses from major life events, such as winning the lottery or sustaining a debilitating injury, tend to be short-lived (Clark et al., 2008). Nevertheless, despite the finding that life circumstances account for only a small portion of individual differences in happiness (Diener et al., 1999), research on the objective correlates of happiness has revealed a number of important links between subjective well-being and such factors as wealth, spirituality, and social relationships.

As it is with most life circumstances, the relationship between wealth and well-being is nuanced and often unexpectedly small. Contrary to popular perceptions that more money is the key to greater happiness, more money appears to be more important for avoiding unhappiness: At income levels above those needed to fulfill basic sustenance needs, increasing income is not strongly associated with more positive feelings (Diener and Biswas-Diener, 2002; Myers, 2000). At the global level, income is associated with well-being far more strongly between nations than within them: People in wealthier nations tend to be happier, on average, than people in less developed countries, but the wealthiest people in a nation are not necessarily happier than their poorer compatriots (see Diener and Biswas-Diener, 2002). Furthermore, wealth is more strongly associated with certain kinds of well-being than with others: Both personal and national income are highly correlated with global life evaluations, but only modestly so with positive feelings (Kahneman and Deaton, 2010). Challenging these findings, however, recent research has found that increases in household income, but not national income (i.e., gross domestic product), are associated with sustained increases in subjective well-being (Diener et al., 2013).

Despite the weak correlation between general life circumstances and well-being, two objective psychosocial variables have consistently been found to be important to happiness. First, as mentioned earlier, people with strong, close social relationships tend to have high levels of happiness and psychological health (e.g., resilience to stress) (Myers, 2000). For example, married individuals in 16 nations reported higher levels of well-being than nonmarried individuals (Stack and Eshleman, 1998), although the happiness boost from getting married does not often persist past the first few years of marriage (Lucas et al., 2003; Lucas and Clark, 2006). Second, when controlling for other life circumstances, religious people tend to be slightly happier than nonreligious people, a relationship that may be due to greater social support and feelings of purpose from religious activity (Diener et al., 2011; Ellison and Levin, 1998).

Hedonic Adaptation as a Barrier to Well-Being

The relatively small impact of life circumstances on well-being may be due to the phenomenon of hedonic adaptation. People experience boosts in well-being following positive life events and declines after negative ones, but, interestingly, these shifts in well-being do not last. A growing literature has shown that individuals become accustomed to changes in their lives via hedonic adaptation (Frederick and Loewenstein, 1999). How rapid and how complete this adaptation is differs for negative versus positive experiences. To begin, longitudinal panel studies suggest that individuals have a remarkable capacity to adapt to traumatic life events, such as disability, widowhood, and unemployment (Clark and Georgellis, 2012; Lucas, 2005, 2007), although the amount of adaptation depends on the individual and the type of event. Some studies have found that individuals only partially adapt to events such as divorce (Lucas, 2005) and widowhood (Lucas et al., 2003), whereas others have found evidence for complete adaptation following these adverse negative events (Clark et al., 2008).

By contrast, the evidence is fairly consistent that people, on average, adapt completely to major positive life changes such as getting married, acquiring a new job, and even winning the lottery (Boswell et al., 2005; Brickman et al., 1978; Clark and Georgellis, 2012). This tendency to adapt to positive events explains in part why changing one's circumstances (e.g., receiving a raise) contributes little to a person's well-being. Although adaptation to many circumstances may be evolutionarily adaptive, becoming accustomed to positive changes in one's life is an obstacle in the pursuit of happiness (Lyubomirsky, 2011).

Increasing Subjective Well-Being

The fact that happiness is heritable and impacted only minimally by life circumstances does not mean that it cannot be intentionally and effortfully increased (Lykken, 1999; Lyubomirsky et al., 2005b). By observing the behaviors that happy people naturally engage in, researchers have found that happy individuals are not passive actors in their lives. Relative to their less happy peers, they seek out rewarding situations (Luhmann et al., 2013), interpret ambiguous events positively, and perceive the silver lining and reappraise negative situations (Lyubomirsky, 2001). This research suggests that happiness is not necessarily static, and that the activities individuals engage in are likely to influence their well-being. If naturally happy people perform particular behaviors, then deliberately choosing to perform those behaviors may increase well-being in less happy people. As such,

observations of happy people have steered researchers to specific ways to increase happiness and informed the designs of future interventions.

Interventions

Happiness is highly valued in cultures around the world (Diener, 2000) and is a subject of great interest to the general public. Fortunately, in recent years, growing work has revealed multiple ways that ordinary people can boost happiness in their daily lives. Specifically, researchers have designed positive activity interventions, which prompt participants to engage in brief, simple, self-administered activities, as an approach to increase well-being and uncover the mechanisms underlying their success (e.g., motivation, effort, and dosage). Many of these activities, such as doing acts of kindness, predicting a positive future, and expressing gratitude, are modeled after the behaviors that naturally happy people do. Notably, a meta-analysis of 51 randomized controlled experimental interventions has found support for the efficacy of positive activities both to increase well-being and to decrease depressive symptoms (Sin and Lyubomirsky, 2009). These efficacious intentional activities include writing letters of gratitude (Boehm et al., 2011; Lyubomirsky et al., 2011; Seligman et al., 2005), counting one's blessings (Emmons and McCullough, 2003; Froh et al., 2008), performing acts of kindness (Dunn et al., 2008; Layous et al., 2012; Sheldon et al., 2012), and practicing optimism (Boehm et al., 2011; Lyubomirsky et al., 2011).

Expressing Gratitude

Gratitude is the felt sense of thankfulness and appreciation toward an individual who has done something above and beyond what is expected or required (Emmons, 2008). Researchers typically induce gratitude in participants by prompting them to count their blessings (i.e., list things for which they are grateful) or write gratitude letters to important people in their lives. One random controlled intervention found that participants who counted their blessings felt better about their lives as a whole, were more optimistic about the coming week, complained less, and exercised more than did controls (Emmons and McCullough, 2003). Expressing gratitude was also found to reduce negative affect and increase positive affect. Another study randomly assigned participants over the course of 6 weeks either to write letters of gratitude to friends or family members who had done something for which they are grateful or to write about neutral weekly experiences (Boehm et al., 2011). Participants who expressed gratitude experienced relatively greater increases in satisfaction with life. The expression of gratitude may allow people to savor the positive experiences and situations in their lives and thus extract the maximum amount of satisfaction from them. Furthermore, gratitude may lead an individual to strengthen social bonds and friendships with others (Algoe et al., 2010) and to be inspired to pay back their benefactors by being a better person.

Performing Acts of Kindness

Naturally happy people report performing more altruistic acts, spending more time helping others, and helping their colleagues at work (Lyubomirsky et al., 2005a). Kind acts are often described as behaviors that are not expected or required and involve some sacrifice in effort, time, and energy (Sheldon et al., 2012). A study by Dunn et al. (2008) found that participants randomly assigned to perform a kindness for another person (i.e., spend money on him or her) reported greater happiness than those assigned to do a kind act (i.e., spend money) for themselves. One possible account of this finding is that kindness tends to increase one's evaluation of oneself as a good person (Williamson and Clark, 1989). For example, after performing acts of kindness for another person, an individual may begin to view himself or herself as a compassionate, helpful person and thus increase in feelings of confidence and efficacy. Furthermore, kind acts may foster social rewards. For example, in a 4-week intervention, 9- to 11-year-old children were randomly assigned to perform three acts of kindness or to visit three places (the comparison group; Layous et al., 2012). Participants also listed classmates with whom they would like to spend time. Children who performed three acts of kindness were significantly more likely to be socially accepted by their peers. This finding suggests that people who perform acts of kindness may not only become happier but better liked by others.

Visualizing Best Possible Selves

Happier individuals are more optimistic and view their lives in more positive ways (DeNeve, 1999; Lyubomirsky, 2001). Furthermore, research has found that individuals prompted to practice optimism show increases in well-being. In one study, participants were instructed to write about their best possible selves – an activity that compels optimism about the future – and complete measures of SWB every day for 4 days (King, 2001). Cultivating optimism led to an increase in happiness that persisted at least until the 3-week follow-up. In another study, participants wrote narratives about their best possible future self with regards to family, friends, hobbies, career, romantic partner, and health – a different domain each week (Boehm et al., 2011). Those prompted to express optimism experienced relatively higher satisfaction in life across time. This activity may lead to greater happiness because it allows people to learn about themselves, restructure their priorities, and gain insight into their motives and desires.

Current and Future Directions

Over the past several decades, researchers have developed and tested a variety of positive activities that happiness seekers can practice. However, much of the research conducted thus far has relied on self-report measures of well-being. This approach can be problematic because self-report measures are subject to social desirability and memory biases (Diener et al., 2009). To this end, investigators are beginning to use more objective and unobtrusive measures of well-being. For example, Chancellor et al. (in press) conducted a study using technology that assessed participants' behavioral rhythm throughout the day over 6 weeks. In this study, behavioral data were collected using sociometric badges that monitor how an individual's body oscillates in three-dimensional space. These badges are sensitive enough to differentiate between a range of movements, including sitting, walking, and talking. The researchers found that participants who wrote down "three things that went well at

work" each week came to the office with more energy and engaged in less office chitchat than those who wrote down three tasks that they accomplished (Chancellor et al., in press).

The rapid growth in technology in recent years has revealed a largely untapped potential for new methods of measuring well-being. For example, the popularity of Facebook™ and Twitter™ gives researchers the opportunity to collect massive data sets from large diverse samples by coding updates for such variables as positive language, emoticons, and humor (see Young et al., 2009; Hughes et al., 2012). New technological advances have also led to innovative devices, such as the Electronic Activated Recorder, that allow researchers to obtain snippets of conversations throughout the day. These recordings can be coded for humor, laughter, or positive words to achieve a clearer and more precise portrait of naturalistic fluctuations in well-being – and its antecedents, correlates, and consequences – over the course of the day (Mehl et al., 2010).

Although subjective well-being is highly valued around the world, a great deal of cross-cultural variation has been observed (Diener, 2000). Some research suggests that carrying out specific positive activities may not be as accepted or endorsed in non-Western cultures. For example, one study found evidence to suggest that Asian-Americans benefit less from practicing gratitude and optimism (Boehm et al., 2011). In another set of studies, U.S. participants, but not S. Korean ones, reported increased well-being after writing gratitude letters (Layous et al., 2013). One possibility is that expressions of gratitude may elicit feelings of guilt or indebtedness in members of Eastern nations. Cultures vary on numerous dimensions, such as individualism/collectivism, power distance, hierarchy, and strength of the economy. Future research could inform positive interventions by considering how such cultural dimensions predict the extent to which individuals might benefit – or even be harmed – by positive activity interventions.

The scientific study of happiness has come a long way since Aristotle proclaimed that it is the meaning and the purpose of life, the whole aim and end of human existence. In the past several decades, researchers have developed valid and reliable measures to assess well-being, explored its correlates, determinants, and consequences, and revealed the ways and mechanisms by which it can be increased. Policy makers around the world have become concerned with the well-being of their citizens, and companies have become invested in implementing programs to boost the morale and well-being of their employees. As interest in happiness continues to spread, research on well-being will begin to inform social policies in countries around the world. Therefore, although research on well-being has a short past, it has a lengthy future.

Sub-Saharan African Legal Traditions

Tinenenji Banda, Cornell Law School, Ithaca, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Sub-Saharan African legal systems are pluralistic in nature and incorporate an amalgam of heterogeneous influences. These states face the ongoing task of reconciling and maintaining these diverse legal traditions in a constitutionally compliant and structurally cohesive way. This article traces the inception of legal pluralism in sub-Saharan Africa and explores the various tensions and complexities created by the complex interplay of ostensibly opposed systems of law and the attendant quest to balance completing values in the context of a unique mélange of legal cultures and tradition.

The concept of law in sub-Saharan Africa is multidimensional, and the simultaneous presence of disparate legal systems operating within the same composite space is a defining feature of its legal tradition. Indeed, all African legal systems are pluralistic in nature and incorporate varied heterogeneous influences that reflect an amalgam of African customary law, religious law, received law, legislation, and more recently, the interaction of international norms with local legal systems.

Legal pluralism with its various contradictions and convulsions has created a variety of challenges as well as opportunities for postcolonial African states that have, in the main, matured into constitutional democracies. These states face the ongoing and nebulous task of reconciling and maintaining these diverse legal traditions in a structurally cohesive way, while allowing these legal systems to operate in a way that does not fall short of constitutional imperatives and human rights obligations.

This article seeks to explore the pluralistic nature of the sub-Saharan legal tradition and the competing interests generated. The aim is not to give a comprehensive discourse on the operation of legal pluralism in sub-Saharan Africa – as that would require a more extensive substantive project, neither is it to assert that these pluralistic experiences are uniform. The goal is rather to explore the various tensions and complexities created by the complex interplay of ostensibly opposed systems of law and the attendant quest to balance competing values in the context of a unique mélange of legal cultures and tradition.

The article proceeds as follows: First, African customary law, the founding legal tradition of sub-Saharan Africa, is introduced. Here, the defining features of customary law are described. Next, the genesis of legal pluralism as legal transplants imported from the colonizing powers is explained. A discussion of the landscape of the postdemocratization legal traditions of sub-Saharan Africa follows. Finally, the interesting challenges that legal pluralism generates in the modern post-democratic sub-Saharan African state are examined. Here, the focus is on the intersection of customary succession law with modern constitutional imperatives and human rights norms using South Africa as a case study.

African Customary Law: The Founding Legal Tradition

Prior to the advent of colonialism, the sole legal tradition of sub-Saharan Africa was what is described today as 'African customary law.' African customary law still governs many sub-Saharan African populations today and remains a widespread and dominant legal tradition.

The singular source of customary law is social practice as exercised by indigenous populations and as passed down from generation to generation through oral tradition (Bennett, 2008). For indigenous populations, custom is law.

While it may be tempting to envisage precolonial African customary law as a singular concept, it was by no means such; rather its content differed among different tribal groupings and it was an eclectic mix of varying ethnic norms and practices.

Distinct Features of African Customary Law

Arguably the most notable difference between African customary law and received law (whether common or civil) is that while the subject of the latter is the individual, the main concern of customary law is the preservation of the cohesiveness of the community and kinship rights. As noted elsewhere, "in traditional African Societies, the individual citizen is primarily seen as a link of a community-chain … the full respect of social order and the necessity to achieve group harmony are crucial values which must be maintained" (Frémont, 2009: 150). The distinct interest of African customary law is therefore the community and not the individual. Individual rights are subservient to broader communitarian objectives, and this greater concern with building consensus within the community is the golden thread that runs through the normative framework of African customary law.

This communitarian approach is probably best understood by examining the dispute resolution systems of indigenous African legal systems. Unlike the adversarial approach of modern legal systems where litigants vie before an ostensibly impartial arbiter who settles the question, dispute resolution in African customary law is conciliatory and involves the community, not just the disputing parties (Owasanoye, 2001). This method seeks first and foremost to preserve social harmony. With this approach, adversaries are encouraged to devise their own solutions with the assistance of the community, and in particular, 'the elders,' who are a prominent feature of traditional African dispute resolution and viewed as a bastion of wisdom, experience, and good judgment (Owasanoye, 2001).

Another key feature of African customary law is that in its most authentic form, it is unwritten. By definition, African customary law is the "unwritten African traditional law which

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86140-1

consists of a variety of different types of principles, norms and rules …"(Assefa, 2012). As noted above, the elders are the repositories of the various norms and regulations of customary law and these norms are passed on orally.

It is thus not entirely possible to ascertain the precise content of African customary law at any given time in history. While this may seem like a recipe for anarchy when viewed in light of the Western understanding of law as a predominantly written amalgamation of rules and regulations, it is precisely this aspect of customary law that is its greatest strength, making it dynamic, amenable to change, and capable of adapting in the face of changing realities, without the long, expensive, and sometimes politically charged process of changing official law (whether through precedent or enactments).

While several African regimes have attempted to codify customary law, the net result of these efforts is often that what is actually practiced on the ground by the indigenous populations years after codification, bears little resemblance to the customary law as it exists in codified, ossified form (*Bhe v Magistrate Khayelitsha, 2005*).

This process of capturing and fixing customary law was a prominent feature of apartheid South Africa. Of course codification had a practical appeal; it aided the ascertainment and proof of customary law and as such made it easier to administer. However, the injustice done to customary law through codification was well noted by the Constitutional Court of South Africa in the landmark decision of *Bhe v Magistrate Khayelitsha* (2005) when it held that:

> because of the dynamic nature of society, official customary law as it exists in the text books and in the Act is generally a poor reflection, if not a distortion of the true customary law. True customary law will be that which recognizes and acknowledges the changes which continually take place.

The *Bhe* court went on to endorse the observations of African customary law expert Tom Bennett in holding that "a critical issue … about customary law will therefore be the question [of] whether a particular rule is a mythical stereotype, which has become ossified in the official code, or whether it continues to enjoy social currency" (Bennett, 1997).

Another distinct feature of African customary law is the manner in which it is administered. Indigenous customary law is administered by traditional leaders known as chiefs, kraal heads, and headmen who ascend to these positions through lineage. As alluded to earlier, traditional leaders in precolonial Africa were seen as custodians of the customs, values, and aspirations of the people and presided over disputes and social institutions like marriage. While traditional leaders continue to preside over customary law today, these leaders are now, in almost all cases, regulated by statute and as such the debate on the proper role of the traditional leader in a postcolonial modern African state is an ongoing one (Rambe and Madwere, 2011).

The Genesis of Legal Pluralism: Legal Transplants

Virtually all nations of sub-Saharan Africa are former colonies or protectorates. When the former colonial powers first descended upon the various African territories, the customary legal system described above was already in operation within these native communities. These laws governed far-reaching aspects of traditional life including property, succession, crime, and family life.

However, the advent of the colonialists and their attendant interests required a reordering of indigenous African institutions. Interestingly, the colonial powers did not do away with customary law but allowed it to continue operating, provided it did not impinge on their commercial or political interests (Bennett, 1982). Their reasons for doing so were of course strategic. It made both economic and political sense to preserve these institutions, as dismantling them forthwith would have placed an enormous strain on the colonial powers, which were already stretched both financially as well as in terms of human capital (Allott, 1970). Moreover had the customary law systems been summarily done away with, language and cultural barriers may have rendered the majority of African communities ungovernable.

Initially, the question of how the two legal systems (African customary law and European law) would apply was resolved fairly simply: European law would apply to Europeans and their business partners, while indigenous law would apply to native Africans (Seidman, 1969). However as time progressed, this dichotomy proved to be too simplistic. Conflicts of laws soon arose as Europeans and Africans began to have increased economic dealings with one another, and as Africans urbanized and began to adopt a Western lifestyle. The colonial administrators soon realized that a more complex mechanism to deal with this burgeoning pluralism was required (Bennett, 1985).

The manner in which choice of law rules evolved in the colonies reflected the different governing styles and legal traditions of the colonial powers. The French, the Belgians, and the Portuguese, who were of the civil law tradition, took an assimilative approach in the colonies they controlled, and crafted choice of law rules that reflected this assimilationist policy (Robert, 1959). However, the British, who were common law adherents, were not predominantly concerned with the assimilation of the local populations, but rather pursued a policy of 'indirect rule'; they adopted choice of law rules to promote this governance style (Gifford et al., 1971).

The Civil Law Colonies

In the African territories governed by colonies following the civil law tradition (France, Portugal, and Belgium), the choice of law rules were determined by looking at the legal status of the litigant (Robert, 1959). In the French colonies, the distinction between persons of *statut coutumier* status (customary status) and those of *status civil francais* (civil status) grounded the choice of law framework (Gifford et al., 1971; Salacuse, 1969).

Salacuse (1969) and Robert (1959) explain how the French colonies dealt with native Africans and customary law. By decree, it was established that all legal matters arising between African litigants must be governed by customary law, while legal matters arising between litigants with civil status (initially only Europeans) would be governed by civil law.

Thus the status of the litigants was the only consideration. It was left to the courts to extrapolate on this basic choice of

law rule in individual situations that required a more complex approach. The status of a litigant was determined by citizenship, which was in turn determined by race. If a person was of European origin, they were considered a citizen and therefore civil law applied. If the person was of African descent, they were not a citizen and customary law applied.

Prior to 1946, it was impossible for an African to be considered a citizen unless they underwent a naturalization process sealed by an administrative or judicial act. In order to be naturalized, an African had to demonstrate that they were of good moral character, had attained a basic level of education or served in the military, had renounced customary law, and was not part of a polygamous marriage. When this was proven to the satisfaction of the governing authorities, an African could be granted citizenship and civil law would govern his or her affairs.

In 1946, the method by which indigenous Africans in the French-administered colonies could be granted civil status was changed. Through two enactments, all French subjects in overseas territories were granted citizenship subject to the proviso that those who did not renounce their personal status retained that status and did not attain French civil status. And then in 1955, the law was again changed to allow any African over the age of 21 to renounce his or her customary status by means of a declaration of a court applying French law. However, the proviso that such person could not be a party to a polygamous marriage was retained. It also had to be shown that the subject had been notified of the irrevocable consequences of the revocation. The French therefore pursued an all or nothing approach. If a subject attained civil status, their revocation of customary law was complete and final.

Similarly in the Belgian-controlled territory of the Congo, the 1908 Colonial charter gave express recognition to customary law, but also provided that Africans could renounce customary law and become subject to civil law by way of a process called "immatriculation" (Robert, 1959).

In the Portuguese-controlled territories, while African customary law was recognized, it was seen only as a transitory measure pending the full assimilation of Africans into the Portuguese way of life. An African could attain civil status through exercising one of two options. The first was a partial acceptance of civil law, in which civil law would administer limited aspects of one's estate (property, inheritance, contracting, and family) and the second option was a full acceptance of civil status in its totality and a total and irrevocable renunciation of customary law (Robert, 1959). In order to exercise the second option, one had to be 18 years or older, fluent in Portuguese, employed, and not an evader of military service (Robert, 1959). Application was made through a court-administering Portuguese law. Later, in 1953, a decree was passed to provide that metropolitan Portuguese law would be applied to every inhabitant of a Portuguese territory whether inland or overseas (Robert, 1959).

The Common Law Colonies

In the Anglophone colonies, however, the race or the personal status of the litigant was not the principal thing used to determine which law would apply to a particular individual, rather the subject matter of the case was the most important consideration. In addition, the choice of law system adopted differed in varying British colonies. In West Africa, for instance, Section 19 of the Gold Coast Supreme Court Ordinance No. 4 of 1876 provided that

> such laws and customs shall be deemed applicable in causes and matters where the parties thereto are natives of the Colony, and particularly, but without derogating from their application in other cases, in causes and matters relating to marriage and to the tenure and transfer of real and personal property, and to inheritance and testamentary dispositions, and also in causes and matters between natives and Europeans where it may appear to the Court that substantial injustice would be done to either party by a strict adherence to the rules of English law.

However in East Africa, Sections 3 and 4 of the 1897 Native Court Regulations held thus:

> The native courts … shall, as far as practicable … be guided by, and have regard to any native laws and customs not opposed to natural morality and humanity. The native courts … shall be guided, subject to the provisions of these regulations, by the native laws or customs existing in their respective jurisdictions.

As can clearly be seen from the excerpts above, in contrast to what obtained in the civil law countries, the Anglophone choice of law system was not concerned primarily with race, but rather with the subject matter of the transaction. Moreover, in certain situations where an African was following what could be deemed a Western lifestyle, English law could be used to govern their affairs without the detailed renunciation process required in the civil law colonies (Bennett, 1982). Partial application of the common law was also acceptable; it was entirely possible for one to have English law apply to his commercial transactions, for instance, but to choose customary law for his marriage and other personal affairs.

In the Anglophone territories, where a conflict between customary law and common law arose, the common law trumped customary law (Ndulo, 2011). However, where there was no conflict, customary law were not tampered with unless a particularly customary law rule was found to be 'repugnant.' The repugnant aspects of customary law were dealt with through the introduction of repugnancy clauses. (Ndulo, 2011). These clauses were enacted in virtually all the Anglophone colonies.

In its basic form, the repugnancy clauses prohibited the enforcement of a customary law rule that was 'repugnant to natural justice, equity, or good conscience.' Explaining what he understood to be the necessity of the repugnancy clause, Lord Atkin in the case of *Eshugbaye Eleko v. Government of Nigeria (1930)* stated that "[T]he court cannot itself transform a barbarous custom into a milder one. If it stands in its barbarous character it must be rejected as repugnant to natural justice, equity and good conscience."

Ultimately, the British settlers gave themselves authority to "establish such laws, institutions and ordinances, and to constitute such courts and offices as may be necessary for the peace, order and good government (Section 1 of the British Settlements Act 1943)" in the territories under their control.

But, as noted above, this far-reaching authority was not exercised in a way that did away with African customary law. While certain aspects of customary law were done away with through the use of the repugnancy clause, most aspects were preserved.

Hybrid Colonies

Hybrid colonies are those sub-Saharan nations that were colonized by more than one power, South Africa and Namibia being cases in point. Namibia was colonized by the Germans from 1884 to 1915 and then by South Africa from 1915 to 1989 (Ruppel and Schlichting, 2011).

South Africa's colonization history is less straightforward. South Africa was first occupied by the Portuguese in 1488, but the Portuguese settlers did not establish or claim it a colony (Thompson, 1990). In 1652, the Dutch East India Company arrived in the Cape of South Africa and established a settlement. The British entered the scene in the 1800s and captured the Cape from the Dutch (the 'Boers'), and in 1803 established sovereignty in the area. Soon the Dutch grew weary of British sovereignty and embarked upon a 'Great Trek' – a mass movement into the interior of South Africa in search of independence from the British (Thompson, 1990). As this movement occurred, the Dutch clashed with African tribes and experienced several crushing defeats at the hands of Zulu warriors (Thompson, 1990). However, they persevered in their quest for independence and established Boer republics in the Transvaal and the Orange Free State (Farwell, 1976). Tensions between the British settlers in the Cape and the newly formed Dutch colonies lead to two installments of an Anglo-Boer war that occurred between 1877 and 1902 (Farwell, 1976). A truce was reached in 1902 and in 1909, the Union of South Africa, a conglomeration of British-controlled territory and Boer republics, was born (Farwell, 1976).

South African law is thus an amalgamation of Roman Dutch law, English law, and African customary law. Prior to the new constitutional dispensation of 1994, African customary law had second-class status in South Africa, but this has since changed and the South African Constitution places customary law on an equal footing with the common law. Namibia as a former South African colony is similarly pluralistic.

The Postdemocratization Era

While the dismantling of colonialism across the African continent in many cases led to a 'romanticized notion of restoring [true] customary law,' it was indisputable that the received law had had an indelible and irreversible effect on the former colonies (Quarmyne, 2011). Even after attaining independence, the former colonies retained the received law and did not revert back to the precolonial era of universal application of African customary law. A legal transplant had occurred. And, even though in most independent states African customary law continued to enjoy recognition and in some cases was elevated to equal status with the received law, legal pluralism had become the hallmark of African legal systems.

The former civil law colonies for the most part did away with the distinction between civil law and customary law and instead created a unified code of law that is an amalgamation of civil law and customary law and is applicable to all citizens (Bennett, 1982). The common law countries including Namibia and South Africa have maintained pluralistic legal systems in which common law and customary law exist side by side. What one finds in most of these sub-Saharan African countries then is an amalgamation of laws from disparate sources and these sources are typically listed in the Constitution.

In Ghana, for instance, a former British colony, the Constitution lists the country's sources of law as follows:

"The laws of Ghana shall comprise (a) the constitution; (b) enactments made by or under the authority of the parliament established by this constitution; (c) any Orders, Rules, and Regulations made by any person or authority under a power conferred by this Constitution; (d) the existing law and (e) the common law." The Ghanaian Constitution goes on to state that the common law includes customary law (Chapter 004 of the Constitution of the Republic of Ghana).

In Zambia, the Constitution of the republic avers that the Laws of Zambia consist of:

1. this Constitution;
2. laws made by or under the authority of Parliament;
3. any orders, rules, regulations, and other statutory instruments made by any person or authority under a power conferred by this Constitution or any other law;
4. the British laws and statutes, which apply or extend to Zambia as prescribed by an Act of Parliament;
5. Zambian customary law, which is consistent with this Constitution;
6. the common law of England, which is consistent with this Constitution;
7. the rules of law generally known as the doctrines of equity; and
8. the law as determined by the superior courts (Section 14 of the Constitution of the Republic of Zambia).

The sources of law in other countries are not dissimilar and it is clear that sub-Saharan African legal systems are heavily pluralistic.

The Survival of African Customary Law

Legal pluralism can and does pose several interesting challenges in the modern postdemocratic sub-Saharan African state. There pluralistic systems often interact and transpose upon one another in ways that are anything but neat and circumspect. There are, for instance, inherent tensions between African customary law and the human rights norms that many African states have voluntarily subscribed to. Embedded within African customary laws are various practices that are discriminatory in nature in their application to women, for instance. Some of the more hotly contested issues include bride price, polygamy, and primogeniture.

For constitutionally democratic African states, the challenge is and continues to be how to preserve customary law (which in most cases is constitutionally protected) and the rights of indigenous populations to be governed by it, while simultaneously ensuring that its practice is in consonance with constitutional and human rights imperatives. As noted by

Bennet in reference to the South African context "[B]y implicitly recognizing customary law … the Constitution has brought about a head on confrontation between two opposed cultures, admittedly a confrontation that has long been gathering force" (Bennett, 1994).

So, for instance, while most sub-Saharan African Constitutions contain an equality clause that prohibits discrimination, the protection of African customary law (which is inherently discriminatory in several respects) is also guaranteed by the Constitution. This creates a conflict that the text of the Constitution often does not provide a mechanism of resolving. So, for instance, the Zambian Constitution in article 23 (2) states that no person shall be treated in a discriminatory manner, but this is qualified by s 23 (6) (d) that permits discrimination "for the application in the case of members of a particular race or tribe, of customary law with respect to any matter to the exclusion of any law with respect to that matter which is applicable in the case of other persons."

The area of succession and inheritance norms provides an apt example of the clash between customary law and broader normative considerations of equality under the law and will now be considered in some detail.

The rule of male primogeniture features in almost all customary law succession systems. The basic tenet of the rule is that only male heirs are entitled to inherit property to the exclusion of females. In recent times, this has come under judicial scrutiny and African courts have been forced to grapple with the question of whether such a rule can stand scrutiny under the equality clauses (and in some cases bill of rights) that are a prominent feature of almost all postcolonial African Constitutions. The contentiousness of the issue lies in the fact that customary law is constitutionally protected and is a recognized and enforced system of law in all post-democratized constitutional African states.

In some African nations, the repugnancy clause has ironically been retained as a mechanism to deal with the aforementioned clash. As noted above, the British colonialists used a repugnancy test to determine which aspects of customary law should be done away with. The repugnancy clauses were and still are controversial, because they ignite old debates about Western universalism and cultural relativism. What is interesting is that the language of repugnancy has for the most part been retained by African courts and African customary law is still in many instances subject to this test even postdemocratization.

For example, in *Mojekwu v Mojekwu* (1997) the Nigerian High Court examined the Nnewi custom, which dictated that if a man died and was survived by a female child or children and not a male child, the deceased's brother or brother's male descendants were the rightful heirs. In the case in question, the deceased had a daughter who was excluded from inheriting from her father's estate in favor of her late-father's brother's son. Using the language of repugnancy, the court held:

> Any form of societal inhibition on grounds of sex, apart from being unconstitutional, is antithesis to a society built on the tenets of democracy which we have freely chosen as a people. On my part, I have no difficulty in holding that the 'Oli-Ekpe' custom of Nnewi is repugnant to natural justice, equity and good conscience.

Repugnancy aside, what is clear from an observation of the jurisprudence of many African courts is that certain aspects of customary law are being invalidated in favor of constitutional imperatives. The courts have frequently used the flexible nature of customary law to justify these decisions. In Botswana, for instance, the Supreme Court in invalidating the rule of primogeniture held concerning customary law.

> …Customary law is not static; it develops and is modernized with the times, harsh and inhumane aspects of custom being discarded as time goes on. More liberal and flexible aspects consistent with the changing ethos being retained and probably being continuously modified on a case by case basis or at the insistence of the traditional leadership to keep pace with the times.…For after all what is customary law but a set of rules developed by society to address issues around certain values which protect the community's social fabric and cohesion … there is no rational and justifiable basis for sticking to the narrow norms of days gone by when such norms go against current value systems.
>
> *Ramantele v Mmusi and Others*, 2012

However, the question of how customary law is to be developed by the courts is one that is a subject of contention. It has been argued that courts have a mandate to develop customary law and not simply obliterate it, and that it is not enough for Courts to pay lip service to customary law but that they have the responsibility to ensure its survival (Mbatha, 2002).

The Case of South Africa

In South Africa, the interesting question of whether the Bill of Rights is directly or indirectly applicable to customary law has arisen with some frequency. The distinction is not a superfluous one, because if the Bill of Rights is directly applicable, the result is that any offending rule must be struck down (Himonga and Bosch, 2000). As Justice Sachs noted in *Du Plessis and others v De klerk and another* (1996) "The direct enforceability of [the bill] could require this Court, if asked to do so, to indulge in a wholesale striking down of customary law because of [its] violation of the equality clause …" (*Du Plessis and others*, 1996). Further, customary law practitioner Alastair Kerr argues in the South African context that "the Constitutional Court would not have certified the Constitution had it thought that in doing so it was bringing about … a destructive confrontation between the Bill of rights … and indigenous law …"(Kerr, 1997).

On the other hand, indirect applicability of the Bill of Rights mandates the court to develop the contravening rule in line with the spirit, purport, and objects of the Bill of Rights in accordance with S 39 (2) of the South African Constitution, which states "when interpreting legislation and when developing the common law or customary law, every court, tribunal or forum must promote the spirit, purport and objects of the Bill of Rights." This approach ensures that an offending customary law rule is not just obliterated but developed.

The constitutionality of the customary principle of male primogeniture as well as the direct or indirect applicability of the Bill of Rights was tested in the South African landmark case of *Bhe v Magistrate Khelitsha* (2005). In that case, the Constitutional Court of South Africa declined to develop the

customary male principle of primogeniture because, according to the Court, such development would create problems of ascertainment. That is, the Court felt that in order to develop the offending customary law rule, the Court would first have to ascertain the breadth of the rule as it was practiced on the ground, and that this would present problems of proof. In light of this, the Court applied the Bill of Rights directly and thus invalidated the rule.

This approach was criticized by customary law scholars who felt the Court reneged on their duty to develop the customary law and instead took the easier route of rendering it invalid (Mbatha, 2002). It was argued that in declining to develop the rule, the Court missed a crucial opportunity to narrow the gap between the official customary rule and the day to day practices on the ground because, as has been observed by Likhapa Mbatha, "… communities that lead a customary life have no problem with allowing a woman to inherit property" (Mbatha, 2002).

Conclusion

Sub-Saharan legal systems are fundamentally pluralistic. This pluralism is a legacy of their colonial past and is reflected in unified civil codes that reflect both customary and received law, as well as in the sources of law typically enumerated in a nation's Constitution. The coexistence of different systems of law has not been without its difficulties. As the place of customary law within constitutional democracies evolves, African courts will continue to grapple with the question of how to preserve what is a distinct African heritage, while complying with constitutional and human rights imperatives.

Suburbanization and Suburbanism

Richard Harris, McMaster University, Hamilton, ON, Canada

Abstract

A global phenomenon, suburbanization entails low-density settlement at the urban fringe. It is caused especially by urbanization, improved transportation, job decentralization, public policy, and a common preference for suburban living. Most suburbs are developed by private agents guided by the state; in the global South many are produced informally by squatters or 'pirate' developers. They take many forms: residential, industrial, mixed; exurban/peri-urban, outer, inner; polycentric, dispersed; planned, unplanned; elite, middle class, low income; and ethnic. Arguably, they reflect and influence suburbanism, a private, family-focused way of life. Surbanization is necessary, and reduces housing costs, but entails major public and private expenditures, reduces farmland, and disrupts ecosystems.

Suburbanization is how urban areas expand and change. It happens when urban populations increase, incomes rise, transportation technology improves, and jobs decentralize. Channeling capital and shaped by private-sector agents, it is usually constrained by municipal regulations and sometimes promoted by governments (Ekers et al., 2012). It takes a variety of low-density physical forms, including sprawl, and involves most types of people. Because it is especially favored by families with children, it is arguably associated with a distinctive way of life, known as suburbanism. It has consequences for population health, the economy, the environment, and municipal governance.

Suburbanization is global but its evolution in the global North and South has been interpreted separately, using different terminology (Angel, 2012; Champion and Hugo, 2004; Harris, 2010; Phelps et al., 2010). The literature on suburbanization has focused on North America and, to a lesser extent, the United Kingdom and Australasia (Clapson, 2003; Palen, 1995; Teaford, 2008). This follows the geographical distribution and interests of urban researchers and publications. Those same researchers have spoken of urban fringe development in the global South in other terms, emphasizing squatter, or other informal-sector settlements. This difference is not surprising. By almost any definition, suburbs first developed in the West. In the nineteenth century, England became the first urban nation – where more than half of the national population lived in urban areas – and the first to see large-scale suburban development, notably around London. In the twentieth century, rising prosperity in the United States created extensive suburban development, which took especially decentralized forms (Schneider and Woodcock, 2008). Because of America's geopolitical influence, and the reach of its media, images of its suburbs are ubiquitous. They have influenced consumers and developers elsewhere, embodying what many still think of as the quintessential suburban form.

Definitions

Definitions are correct only in so far as they are useful. Suburbanization entails the growth of suburbs but, because there is no generally accepted definition of this term, the meaning of both must be explored. The issue is complicated by the fact that, although 'suburb' or equivalent terms is used in many parts of the world, its connotations vary. In the United States, but not elsewhere, a true suburb is politically distinct; this is significant because under the US Constitution, no higher level of government can abolish or amalgamate municipalities without their permission (Nicolaides and Wiese, 2006; Teaford, 2008). In Spanish and Italian-speaking countries, 'suburbio' does not carry strong connotations of prestige, and in France 'les banlieues' are stigmatized. China has no precise equivalent to suburb, and India lacks a generic term. In some sense suburbs exist everywhere, but they are defined and understood variously. Differences of definition and understanding can even exist within a city, perhaps especially in the global South. Western-educated politicians and planners speak of suburbs, but this may have no resonance for residents who speak other languages and have a different understanding of their city's geography.

In the English-speaking world, 'suburb' can mean different things (Clapson, 2003; Forsyth, 2012; Harris, 2010; Palen, 1995; Phelps et al., 2010). A narrow definition, meaningful because influential as a model in Anglo-America and beyond, is that of the low-density, socially exclusive, and purely residential area located at or near the urban fringe. But, in the past as in the present, extensive urban fringe areas have failed to conform to this stereotype. In particular, many house low- and moderate-income households and, although they contain residential subdivisions, they often also include commercial and industrial land uses. And the Anglo-American stereotype is not generally employed elsewhere. In general, two aspects are emphasized: moderate residential density and urban fringe location. These are related but distinct, which raises the unresolved question as to whether a suburb must satisfy both criteria, or whether one takes priority.

Reflecting the fact that land at or near the edge of the built-up area is intermediate in price between urban and rural lands, so too are residential densities. In many cities, the typical urban dwelling is a townhouse (row or terraced) or apartment building, while a suburban home is likely to be detached or semidetached. Collectively, the latter constitute a 'middle landscape' that, depending on one's point of view, marries the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.74044-X

best or the worst elements of city and country (Clapson, 2003; Palen, 1995: 95–99). Commonly, residential densities decline from city center to urban fringe, although this may be complicated in at least two ways. First, where incomes are low and/or land prices are high (e.g., Hong Kong, Singapore, Istanbul) even fringe development may occur as high-rise towers. At the scale of the building, densities are very high, but where towers are widely spaced, area-wide densities are moderate. In regions where land market forces had little influence, including communist-era Russia, China, and central Europe, closely spaced high-rise buildings were erected, so that urban fringe development took an unusually dense character (Hirt, 2012). A second and increasingly common complication is the growth of major, competing centers of employment and retailing in fringe locations. Often known as Edge Cities, these become nodes of higher land costs and building densities. Polynuclear and dispersed growth can create very complex patterns of land use, but in general densities still decline toward the fringe.

Regardless of density, districts may be viewed as suburban simply because they are located near the edge of the built-up area. 'Near' has no precise meaning. Not all urban areas have sharp physical boundaries: sprawl may involve the creation of isolated subdivisions scattered across an 'exurban,' semirural landscape. Then, too, as urban areas expand, districts once located at the fringe will be engulfed by later development; it is difficult and indeed arbitrary to determine at what point they cease to be suburban. Commonly, a distinction is now made between outer-ring and inner-ring ('mature' or 'older') suburbs (Hanlon, 2010). In growing urban areas, outer-ring suburbs will be newly built and settled. Their novelty may be socially significant, but is not usually regarded as a defining characteristic.

Inevitably, suburbanization occurs as the population of an urban area increases. Growth must usually be accommodated mainly through fringe development. There is limited vacant land near the urban center, while redevelopment at higher densities is expensive, in part because it typically involves the purchase and assembly of several land parcels from sometimes-reluctant owners. Most challenging of all, it arouses NIMBY (Not In My Back Yard) opposition, which even authoritarian governments may wish not to arouse. Suburbanization may also be said to occur surreptitiously, as densities everywhere decline. For many decades over the past century, through the demolition of slums, a reduction in average household size, and the relocation of many families to the suburbs, residential densities declined in the central areas and inner suburbs of almost all major cities (Angel, 2012). Densities in some city neighborhoods today are similar to those of outer suburbs a century ago. Now, as outer suburbs boom, it may seem that urban areas are becoming more suburban in character. In that sense, it has been suggested that the United States (or, more probably, Australia) became the first suburban nation. Extrapolating, a world that is now predominantly urban will increasingly become suburban.

Depending on how suburbs are defined, this trend is neither inevitable nor in the long run likely. As urban areas expand, outer suburbs become inner, while inner suburbs become city neighborhoods. In the process, residential areas cease to be, and to be thought of, as suburban. (Even in Australia, where residents refer to city neighborhoods as 'suburbs' everyone recognizes that such areas are physically and socially different from new subdivisions.) It is not just the relative location of inner suburban areas that has changed. Some, especially elite neighborhoods with restrictions that prevent redevelopment, may preserve their character over many decades. But most undergo physical and social changes, typically involving the incursion of new land uses and redevelopment at higher building densities. Much of the residential density decline that has occurred in inner areas over the past century has been due to the conversion of residential to other forms of land use. Now, even in many North American cities, it is reversing: the popularity of condominium tenure since the 1970s has made it possible for people to live at high densities and still own their own homes – a common aspiration. High-rise Singapore has the highest level of home ownership of any major city in the world. In this unobtrusive manner, over a period of decades residential areas cease to be suburban in density as well as location. Whether a city is becoming more or less suburban depends on what balance is struck between unobtrusive 'citification' and the more obvious development of outer suburbs. Currently, in most cities, the balance favors suburbanization. But the larger urbanization process is necessarily finite, while current fertility trends suggest that world population may peak within 50 years. As the population of cities levels off, and especially if environmental considerations favor higher density forms of settlement, the balance will shift, and perhaps dramatically.

Causes

Although many accounts overlook the fact, over the past two centuries the main cause of suburbanization has been the growth of urban populations. In most regions, such growth was promoted by an overall increase in population and also by urbanization, that is, an increase in the proportion of people living in urban areas. Until the mid-twentieth century, because cities were unhealthy, urbanization was driven by rural–urban migration. It still is, most dramatically in China. But recently, in most world regions, improvements in public health have made cities healthier than rural areas. Urbanization, and therefore suburbanization, has depended in part on natural increase.

Suburbanization has happened, and continues to occur, even in the absence of urban population growth, as population densities decline (Angel, 2012). Five related influences are commonly invoked to explain this trend; two others have also been important though often overlooked. Their relative importance has varied across place and time. The most important has been improved transportation technology. At first, railways, horsecars, and then electric streetcars (trams) enabled people to live at increasing distances from centrally located workplaces, clustering along transit lines and around stations. Affluent nineteenth-century railway suburbs, and middle-income streetcar suburbs, resulted. Then, the personalized technology of bicycles, cars, and mopeds/scooters enabled a further, and also more dispersed, pattern of decentralization. Cars began to shape suburbs in North America in the 1920s, Europe after 1945, Latin America in the 1960s, India

in the 1970s, and then China in the 1980s. Automobiles have played such a large role in shaping modern suburbs that many observers view suburbs as places where people rely on them for commuting, shopping, and other errands.

All of these technologies, even streetcars but especially cars, are costly. Their widespread use has depended on rising incomes, initially among the middle class and then for workers. Growing affluence is a second influence on the growth of suburbs, and suburbanization is one of the most visible signs of urban prosperity. The most affluent nations are also the most suburban.

A third major cause of suburbanization has been the decentralization of employment, which has made it possible and preferable for many employees to live in adjacent suburban areas. Although the fact is not always acknowledged, many industries were moving to the suburbs of North American and European cities from the nineteenth century, and by the early postwar era these were soon followed by office employment and retailing (Harris and Lewis, 2001). This trend, too, was facilitated by improvements in transportation, and notably the growing use of truck transportation from the 1920s. At first, workers settled within walking distance of suburban factories in industrial suburbs. This pattern is still common in the global South. Automobiles and mopeds have given employees wider options.

Transportation technology allows, but does not compel, workers to live in the suburbs. If they have chosen to do so, that is because of a widespread preference for suburban life. Where workers also have jobs in the suburbs, this involves no tradeoff. Historically, however, and even today in many cities, workers are willing to spend time and money commuting downtown in order to enjoy the greater quiet, spaciousness, and privacy of suburban living. These features depend on larger homes and gardens, readier access to parks and open space, and removal from centers of commercial activity. Historically, suburbs were also perceived to be healthier, with cleaner air and less industrial pollution. Because of relatively cheap land, suburban home ownership is affordable to more households and that has been a major additional motive. Owner-occupancy is widely preferred because it offers greater security of tenure than tenancy, and more opportunities to adapt domestic space to changing family needs. Transportation technology and decentralizing jobs have made it possible for millions of households to realize their suburban dream.

Recognizing the strength of this popular aspiration, governments have often subsidized it. These usually implicit subsidies, a fifth significant cause of suburbanization, vary greatly in strength by country and take many forms. In the United States, federal support for highway (motorway) construction, coupled with income tax deductions for mortgage interest and property taxes, created unusual subsidies for low-density development. There, and in many other countries, implicit subsidies for all types of road construction, coupled with property taxes that do not reflect the full cost of servicing low-density development, have produced the same effect (Blais, 2010). So too has the general failure of governments to levy effective taxes (betterment charges) on the dramatic price increases that occur when land is converted from rural to urban use (Evans, 2004). This failure continues to provide major incentives for land conversion and development.

A sixth and often overlooked influence on suburbanization has been a delay in the creation of effective methods of public health and for the disposal of human, animal, and industrial wastes. The consequences are usually worst in the most densely settled districts close to city centers, and this has shaped people's belief that suburbs are healthier. In the nineteenth century, the problems of public health were those of ignorance, notably about how diseases spread. Today, the challenge usually faced by municipalities is how to pay for the necessary infrastructure.

All discussions of suburbanization in the global North assume that those who move to the suburbs have chosen to do so, recognizing that in some cases (Paris, New York City, London) their choices are constrained by the unaffordability of centrally located real estate. In fact, some households have had almost no choice at all; involuntary relocation has sometimes been a seventh significant force for suburbanization. In Europe, housing agencies have allocated low-income households to peripheral estates. Often families moved willingly but sometimes not, because peripheral estates were far from jobs and stores, often poorly served by transit, and soon stigmatized. A comparable situation exists elsewhere, for example Delhi, where hundreds of thousands of families, displaced through slum clearance, have been moved to isolated resettlement colonies (Dupont, 2005). The undesirability of these places is underlined by the fact that many residents abandon modest but decent houses and return to cramped squatter quarters in the city.

The Development of Suburbs

Suburban development entails the conversion of rural or unoccupied land to urban use through the legal subdivision of land into smaller parcels, and the laying out of streets. Municipal regulations commonly require the provision of hard infrastructure, notably piped water and sewers, and sometimes services such as schools.

The development and governance of suburbs involves a variable balance of public and private agencies (Ekers et al., 2012). Development is sometimes initiated by a municipality, or public agency. This happened in communist countries, and municipalities in China are still entrepreneurial (Hsing, 2010; Wu and Shen, in press; Zhang, 2010). More modestly, social-democratic governments develop large-scale public housing (Clapson, 2003). In Britain, state agencies built New Towns and suburban estates; in France, modernist projects (*grands ensembles*) defined many banlieues; the City of Stockholm linked comprehensive suburban development to the construction of fixed-rail transit. More typically, municipalities play a permissive and regulatory role. Land use master plans specify which areas may be developed, and for what purposes; building regulations control designs and methods of construction; housing bylaws mandate maintenance; charges levied on developers cover the costs of providing infrastructure, including roads; and property taxes support public services and the maintenance of infrastructure (Evans, 2004). By taxing, or failing to tax, fuel and capital gains, national governments shape the suburbs. Governments at all levels affect the suburbanization process.

Suburban development is usually undertaken by private companies and coordinated through the markets for land, housing, retail, office, and industrial space (Rybczynski, 2008). Today, developers often install infrastructure, which they pass to the municipality for maintenance. An increasingly common alternative is the common-interest development (CID), sometimes gated, where common facilities are owned jointly by property owners who pay fees to cover upkeep (McKenzie, 1994; Nicolaides and Wiese, 2006). Facilities may include play areas, miniparks, pools, community halls, and even roads. Once developed, responsibility for maintenance lies with a homeowner association. Developers may require buyers to sign covenants that govern who may live there and how property is maintained. Many buyers believe such regulations help maintain standards and property values.

Developers usually delegate construction to builders. Because of the large capital investments involved, they rely on credit. To minimize risk, lenders favor conventional schemes and, for ease of later sale, so do home buyers. In any city, region, or nation, most suburban developments – whether of homes, apartments, malls, or offices – conform to a limited range of types. As some lenders and developers now operate across borders, and because some suburban models (such as malls and gated communities) have become popular, standardization is becoming international (Glasze et al., 2006; Rimmer and Dick, 2009).

In North America, Europe, Australasia, and Japan, suburban development occurs within the formal sector: it conforms to prevailing laws and regulations. In many cities elsewhere, informal development is common. Sometimes, squatters settle and build on land they do not own. This is commonest on publicly owned land because governments are wary of evicting citizen-voters. As public lands are growing scarce, squatting is becoming rarer. Instead, a growing amount of suburban development is undertaken by 'pirate' entrepreneurs who acquire and sell land legally, but where residential development is not authorized (Doebele, 1977; Dupont, 2005; Klaufus, 2012). Commonly, these developers fail to install required infrastructure; dwellings, commercially or owner-built, often violate building regulations. Although informal settlements are illegal, they may be tolerated or implicitly encouraged by municipalities because they relieve the shortage of housing for low- and moderate-income families. Around cities in the global South, the formal and informal land markets are interdependent, and together produce suburbanization (Benjamin, 2004; Rimmer and Dick, 2009; Wu and Shen, in press).

Types of Suburbs

Today, any large metropolitan area may include a wide variety of suburbs. How much more this is true of the suburbs of a nation or, even more obviously, the world (Harris, 2010).

Physically, the main dimensions of difference are those of age, land use, pattern of development, and degree of planning. Urban areas expand into the countryside. Occasionally, as with Cairo's desert, fringe territory is unoccupied; sometimes, as with areas of wet-rice cultivation in Southeast Asia, it is densely settled; normally it contains a mixture of farms, villages, and towns. Expanding cities engulf such areas through the dispersal of urban families, seeking space and a rural ambience, or by attracting rural migrants who seek urban jobs but cannot afford urban rents. Dispersal is more common in the global North, where it creates exurbia (Taylor, 2011). Rural–urban migration is the norm in China and the global South, where it helps create what Western researchers refer to as a rural or peri-urban fringe (Simon, 2008; Hsing, 2010). Geographer Terry McGee has labeled the very dense urban fringes of Southeast Asia *desakotas* (villagecities). By whatever name, such areas are the first, presuburban phase of urban expansion. They contain rapidly changing and strangely juxtaposed elements, including truck farms, billboards, villages, waste dumps, individual houses, gravel pits and quarries, small subdivisions, and industry, in no apparent order.

Suburban development emerges with consolidation, or the redevelopment, of fringe development into a continuously built-up landscape. Consolidation involves infill, perhaps in the uncoordinated form of individual houses and small subdivisions. Redevelopment requires planning and often government approval and produces a more uniform landscape. The result is an outer suburb, at first raw, with limited vegetation, new residents, and few services. Such suburbs mature: lawns, bushes, and trees grow; residents adapt their dwellings, introducing variety into standard subdivisions; they make friends of neighbors; stores open and services develop. In time, dwellings may deteriorate or become obsolete; lower income households move in; homes may be subdivided and maintenance declines; and stores change. Regardless, once-outer suburbs become inner, and redevelopment pressure grows. The outcome is unpredictable and, in the United States as elsewhere, inner suburbs are varied (Hanlon, 2010). But in terms of density as well as location, age distinguishes suburbs and adjacent fringe areas.

Although individual suburbs may appear residential in character, all have some nonresidential land, commonly parks, schools, churches, retail activity, and recreational facilities. Retailing may be extensive, taking the form of auto-centered malls or big-box centers. Most suburbs also contain office clusters, perhaps lining highways or major arterial roads, and many have light industry. A surprising number of suburban areas, especially those close to airports or major highways, are dominated by light industry, truck and road crew depots, warehouses, and related activities, and so contain more jobs than resident workers. Suburbs, then, may be classified as 'residential' or 'employing,' or by the main type of employment, whether industry, office, or diversified (Harris and Lewis, 2001).

Suburbs were once oriented toward and subsidiary to cities. This is still the case around small- and medium-sized isolated urban centers. Where such centers form regional clusters, and in large metropolitan areas, it is no longer true. Metropolitan development is now multicentered, as suburban Edge Cities form nodes of office, retail, and government employment, or decentered, as jobs scatter, with only minor clusters at highway interchanges (Phelps et al., 2010). Commonly, in varying degrees, these forms of suburbanization coexist.

Large-scale clustering may reflect metro-wide planning, but Edge Cities can emerge spontaneously. At the scale of the individual suburb or subdivision, the role and degree of

planning is more obvious (Relph, 1987). Suburbs planned by a single developer, or tightly regulated by a municipality, have integrated street plans, nonrandom patterns of land use, and some homogeneity in dwelling types and architectural styles. Postwar suburbs tend to boast curvilinear streets, with loops and cul-de-sacs, and large-scale segregation of land uses. More recent suburbs, including Planned Unit Developments and those inspired by New Urbanism, may combine residential and commercial land use on a connected street network. If organized as CIDs, they may feature fences, walls, and gates. Popularized in the United States, and drawing on local traditions, versions have become common in many cities in emerging economies and the global South (Rimmer and Dick, 2009; Fleischer, 2011; Glasze et al., 2006; Grant, 2009; Hirt, 2012).

At the other extreme, unplanned suburbs may feature incomplete street grids, juxtapositions of incompatible land uses, and modest dwellings built of different materials in varied styles. Irregularity is especially true of those that first developed in exurban or peri-urban areas, where regulation is limited or weakly enforced. These display varied orientations and setbacks from the street. In the case of squatter settlements, lot boundaries may be unclear or absent. Unplanned suburbs were common in North America before the 1930s, and persist in outer fringe areas, around smaller urban centers or, as *colonias*, close to the Mexican border. They are common in Japan, in part because of patterns of land ownership (Sorensen, 2001), in parts of southern and central Europe, and throughout the global South, where many began as informal settlements.

Physical contrasts are often associated with social differences. The stereotypical suburb was once exclusive; it is now middle-class (Nicolaides and Wiese, 2006). Both are typically planned. But working-class suburbs, many unplanned, have always been common, historically around European cities such as Paris, Madrid, Rome, and Athens, and now in informal settlements in China, India, sub-Saharan Africa, and Latin America (Benjamin, 2004; Klaufus, 2012; Wu and Shen, in press). The Anglo-American stereotype is that suburbs are for the native-born, as immigrants settle first in city neighborhoods. This was never wholly true: many North American industrial suburbs were first occupied by Irish, southern European, and eastern European immigrants. Today, many of Europe's lower income suburbs house immigrants, especially from North Africa or Turkey; in the global South, rural migrants bring cultures and sometimes languages that locals view as foreign; in North America, the decline of some inner suburbs has enabled many immigrants to settle there; and waves of prosperous immigrants, notably Chinese, have created ethnic enclaves in outer suburbs, such as Toronto's Markham. In cities such as Accra, Ghana, remittances and expatriates are shaping many outer suburbs (Grant, 2009). Various versions of the ethnoburb are now common.

Suburbanism

Faced with such diversity, it may seem impossible to identify a shared 'suburbanism' or way of life. The term was coined in the 1950s by sociologist Sylvia Fava, in counterpoint to the idea that urbanism, or city living, entailed social anonymity and freedom. But the idea that 'suburbanites' have a distinctive way of life is older, dating from late-nineteenth century London, when 'suburbia' referred to both a type of place and a type of person. Ever since, writers have tried to disentangle the interrelation of built environment and social behavior.

To understand suburbanism we must distinguish the popular mythology from the social aspiration and the lived reality. Propagated by academics and the media, the mythology has varied (Clapson, 2003; Nicolaides and Wiese, 2006: 291–320; Palen, 1995). It has commonly referred to social conformity, and with privatized forms of family living at the expense of higher cultural aspirations. In the United States in the 1950s, it apparently meant enforced socializing with neighbors; now, supposedly, the opposite. Such mythologies were often based on the impressions of well-educated and snobbish outsiders. Ethnographic studies provide valuable corrections to stereotypes (Fleischer, 2011; Grant, 2009; Zhang, 2010). Early research in the United States, for example, showed that elements of the supposedly suburban lifestyle were in fact specific to a social class (Gans, 1968).

Mythologies have often been modified or contradicted by studies of people's aspirations in moving to the suburbs, and of their level of satisfaction and pattern of living after their move. People who move voluntarily to the suburbs do so for a common, if variable, mix of reasons (Michelson, 1977). They want more space within, around, and adjacent to their home; they value privacy; and they believe suburbs are healthier and safer for raising children. Their preference is confirmed where suburban schools are perceived to be better. Prestige is sometimes a consideration. There is a widespread preference for home ownership, although sometimes, as in Singapore and Beijing, this takes the form of condominiums (Zhang, 2010). Socially diverse but demographically unrepresentative, suburbanites have moved for particular reasons. If there is a distinctively suburban way of life, it must reflect these facts.

Evidence indicates that suburban residents are satisfied with their environment. They devote above-average time and money to their homes, and in childrearing. Young families have little disposable income, especially those with mortgages. They entertain in and around the home, and spend little on exotic holidays or cultural events. To save money, and/or as a hobby, they undertake DIY (Do-It-Yourself) house repairs and modifications. In low-density, transit-poor suburbs, especially where both parents work, they need cars. Committed to privatized consumption, they resist taxes and many are fiscally conservative. This is especially true of marginal, self-made suburbanites who often deplore state benefits. The conservative political orientation of suburbanites is not inevitable, but some patterns of expenditure and behavior are strongly associated with suburban living.

These patterns of behavior were mostly anticipated and chosen even if, in the case of auto-dependency and long commutes, not always welcomed (Michelson, 1977). However, evidence suggests that the physical environment negatively guides behavior more than residents expected. This is especially true of the time spent driving, to work, to shop, to school, visiting friends, and running errands, commitments that peak when children reach their early teens, years after parents originally planned their move to the suburbs. Research also indicates that suburban environments discourage active transportation (walking, cycling), promote obesity, and have harmful side effects on health. Although

these influences have been best documented with reference to suburbs in the global North, they are valid in varying degrees elsewhere. The suburban way of life is mostly chosen, but partly imposed by the physical environment.

Such impositions are experienced as confining or intolerable by specific groups. Feminists have pointed that, even when they help make the decision to move, women in one-car families find auto-dependent suburbs confining. This is less an issue in two-car households, although because they still bear primary responsibility for shuttling children around, many women experience an extra travel burden. In general, suburbs are often felt by teenagers to be oppressive, whether because of their social conformity or because they are challenging to navigate without a car and drivers' license. The elderly – those who age in place or those who move in with their children – together with the disabled, may also feel constrained and dependent. Although suburbs entail a certain pattern of living for most residents, they can help prevent the remainder from participating in a full social experience.

Consequences

Beyond its effects on social behavior and health, suburbanization has wider consequences. These vary with residential density, being greatest for sprawl. In regions experiencing rapid urban growth, suburbanization is inevitable. Three effects are especially important: economic, environmental, and governmental.

The lower density environments typical of suburbs are more costly to service with roads, tracks, pipes, and wires, as well as with police and fire protection. They also require large expenditures on personal transportation. Their production requires major capital investments; their maintenance and use demands high property taxes and also municipal and personal debts. This is the cost of obtaining the environment many people prefer. However, because of market distortions introduced by government policy, discussed earlier, the density of suburban development is lower, and its costs greater, than is socially optimal. Directed elsewhere, some investment and expenditure currently channeled into suburbs might raise productivity and the standard of living. Against this, evidence suggests that even in the global North, land and housing costs less in lower density metropolitan places. In many cities in the global South, housing conditions would improve if urban areas were less dense (Angel, 2012).

Another type of economic significance arises from linkages between the urban built environment and flows of capital (Harvey, 1978). Built environments are immobile and enduring, tying up capital for decades. In metropolitan areas that stagnate, their devaluation creates problems for families, companies, investors, banks, and municipalities. In rapidly developing areas, problems can also arise. Booms invite speculative investment. When bubbles burst, vacancies and devaluation may bankrupt individuals and lenders alike, especially during periods of overaccumulation when lending institutions have excess funds to invest. Periodic crises are endemic to capitalism, and the scale of fallout has grown with the globalization of capital markets. The financial crisis of 2008, triggered by overinvestment in suburban real estate in Ireland, southern Europe, and above all the United States, underlined the economic ramifications of suburbanization.

The environmental impacts of suburbanization are also clear. They include the loss of productive farmland, as well as threats to biodiversity and ecosystems, notably wetlands and watersheds. These effects are most apparent in rapidly changing peri-urban zones, but they affect all urban residents (Simon, 2008). Some but not all can be mitigated through planning. Their significance varies greatly, depending on local biota and physiography. Many researchers have focused on the effects of low-density development on energy use, carbon emissions, ozone levels, and climate change. By comparison with smaller homes in denser city neighborhoods that are well served by transit, suburban living leaves a larger carbon footprint. But in many regions, suburbanization is caused primarily by rural–urban migration. Depending on the lifestyles of rural residents, their relocation to suburban and urban fringe areas may reduce carbon emissions. The net effects cannot be taken for granted.

Third, apart from raising infrastructure costs, suburbanization challenges suburban governance. As urban settlement expands beyond municipal limits, outer suburban areas require infrastructure and land use planning that existing local governments cannot provide. Where effective suburban governments do exist, they may adopt land use and other regulatory practices that raise housing costs and exclude suburban living from many people. And under all circumstances, the proliferation of suburban jurisdictions makes effective metro-wide planning of land use and transportation more difficult. In principle, planning can be improved through municipal amalgamation or the formation of specialized metro-wide agencies with wide powers. These initiatives are commonly unpopular among suburbanites. Upper levels of government, which have the power to implement them, hesitate to do so.

Suburbanization is inevitable, and often desirable. The practical challenge is to guide it in ways that minimize the negative social, economic, and environmental effects. This requires the cooperation of municipal and upper levels of government, whether produced by rare political vision, grassroots pressure, or a major crisis.

Successful Aging in Western Societies: The 'Selection, Optimization, and Compensation' Model

Abstract

The processes and outcomes of successful aging are viewed in a life span developmental perspective that emphasizes adaptive person–environment transactions across adulthood and the maximization of gains while minimizing losses. This article is organized around three questions: (1) What is successful aging?, (2) How is successful aging different from normal or pathological aging?, and (3) What are processes that lead to successful aging? – The model of selection, optimization, and compensation points to a standard of optimality in successful life management in old age.

Introduction

The notion of successful aging is a long runner in the field of behavioral and cognitive aging. In more than 60 years, theoretical and empirical research has generated a wealth of findings on adaptive or positive processes of aging. In this vein, there are three pertinent issues: (1) What is the meaning of successful aging, (2) What are criteria that differentiate successful from normal or pathological aging, and (3) What are the processes that bring forth desirable outcomes across adulthood.

Since the early beginnings of empirical research on successful aging, the term was used to describe the ways through which people "become happier, more successful in their pursuit of the goals of life, or better adjusted" (Havighurst and Orr, 1955, p. 477). Already then, 60 years ago, it was widely accepted that successful aging refers to a process rather than merely reflecting an outcome in old age. Today there is a strong agreement that successful aging involves adaptive processes in response to the changing gain–loss dynamics across adulthood that involve a maximization of gains while minimizing potential losses (Baltes and Baltes, 1990; Baltes and Carstensen, 1996; Marsiske et al., 1995).

In addition, successful aging may not be limited to positive subjective experience in old age but also pertains to objective conditions such as health, competence, and functioning (Palmore, 1978; Rowe and Kahn, 1987). However, it is still debated how different criteria of success may be identified in the context of multifaceted challenges in the aging process. For example, in an early study on successful aging Havighurst and Albrecht (1953) observed that good health did not guarantee high levels of social activity or positive psychological adjustment. In the biomedical sciences though, successful aging has been more strongly related to good physical and mental health (Rowe and Kahn, 1987), and also to a high level of functioning of the older individual. In more recent theoretical approaches, there is agreement that successful aging requires both subjective and objective sources of evaluation that rely on age-adjusted norms of judgment (cf Baltes and Carstensen, 1996; Lang et al., 2011; Freund et al., 2013). In line with this, we discuss processes and outcomes of successful aging in a life span perspective that emphasizes adaptive person–environment transactions across adulthood and the maximization of gains while minimizing losses in the course of becoming old. In the following, we organize this article around the following three central questions:

1. What is successful aging?
2. How is successful aging different from normal or pathological aging?
3. What are the processes that lead to successful aging?

What is Successful Aging?

Since the year 1961, about 350 articles and books abstracted in PsycInfo (American Psychological Association) and more than 400 articles in Medline included the term successful aging in the publication title, not counting articles on 'positive aging' or on 'aging well.' In the literature, there exist many definitions of successful aging, and even more heterogeneity with regard to the measurement of successful aging. According to modern dictionaries of everyday language (cf Merriam-Webster Dictionary, Oxford Advanced Learner's Dictionary), *success* is generally defined as an attainment of desired or ideal states, events, or outcomes, that is, wealth, health, or high social status. In the life span sciences success of aging goes beyond such limited views to also reflect the individual's capacity of adaptation and mastery of challenges. In specific, we argue that successful aging pertains to establishing a best possible (i.e., *optimal*) match between an individual's capacities or resources and the individual's contextual demands and opportunities (Baltes and Carstensen, 1996; Baltes and Lang, 1997; Lang et al., 2011; Marsiske et al., 1995). For instance, a just widowed older woman may seek to refresh old social bonds, intensify existing close ties, or seek for new social contact in order to master her personal loss (cf Zettel and Rook, 2004). In general, adaptation to aging-related losses may depend both on personal resources (e.g., sensory functioning, being extra- or introverted) as well as on contextual resources (e.g., access to supporting devices, availability of supporting infrastructure such as access to Internet or the existence of meeting places or self-help groups in the neighborhood).

Most scholars agree that subjective and objective criteria should be integrated in some way when evaluating the aging process (Bowling, 2006, 2007; Depp and Jeste, 2006; Pruchno et al., 2010). However, there is disagreement regarding the relevance and role of subjective evaluations in the process of aging (Brandtstädter and Greve, 1994; Freund et al., 2013; Lang et al., 2011). Surprisingly enough, in their early classic study, Havighurst and Albrecht (1953) defined successful aging as subjective evaluation of the personal aging experience. However, such subjective evaluations of the self may be interpreted in different ways.

Some authors argued that subjective self-appraisals serve to protect the ability to exert control, and may not be used as criteria of successful aging 'in their own right' (Schulz and Heckhausen, 1996, p. 705). Other authors claimed that subjective criteria reflect a positive adaptation of the self that need to be respected even when appearing to be in contradiction to more objective conditions of individuals' aging situation (Brandtstädter and Greve, 1994; Schulz and Hanusa, 1980). In the first perspective, the subjective evaluation of one's aging experience points to potential processes of adaptation. In the latter perspective, the subjective evaluation of an individual's aging situation is seen as an outcome of an adaptation process. Obviously, both perspectives are complementary rather than contradictory. Subjective evaluations of the aging self-reflect both functional processes as well as adaptive outcomes in the process of aging. Successful aging may follow from a correspondence between subjective standards and objective constraints (e.g., happiness in low income contexts; Chung and Park, 2008). Also, successful aging may occur even after stroke when an older person has adjusted well psychologically and physically in a life with handicaps and limited autonomy (Donnellan et al., 2012). This means that successful aging may not be limited to the pursuit of happiness or life goals, but rather should also reflect an *optimality* norm. Optimality, in this vein, is defined as a standard of *best practice* given the individual's available resources and contextual challenges.

Many theories on successful aging emphasize contextual demands and constraints associated with adaptation in later adulthood. According to such theoretical approaches, successful aging is reflected in the ecology of the older individual and the proactive coconstruction of person–environment fit (Lang et al., 2011; Kahana and Kahana, 1996; Schulz and Hanusa, 1980). This means that definitions of what is positive, adequate, or functional in old age should consider the respective contextual challenges and resources of the aging person. For example, the ability to drive a car may be more essential in a rural area as compared to a metropolitan area where persons may rely on a more developed public transportation system or a better infrastructure. Conditions of successful aging may differ between cultures, but the contextual demands may at times differ strongly within one culture. In this vein, images of successful aging, and the ascribed responsibility for aging well may vary across cultures and cohorts (e.g., Levy and Langer, 1994; Hess, 2006; Kotter-Grühn and Hess, 2012).

On a more general level, the ecology of aging may often entail contextual resources that serve to activate, enhance, and maintain adaptation in the process of successful aging. Illustrations for such contextual regulation of adaptation in old age pertain to social, medical, and technological advancements in modern societies, ranging from improved health care services to new prosthetic technological devices (Lang et al., 2011; Lindenberger et al., 2008). For instance, in most aging societies new societal structures evolve that provide novel options for social participation, mobility, and education for older adults. New opportunity structures generate proactivity in the selection of goal engagement or the refinement and exercising of competence, in addition to prosthetic or supportive environments. One way of how the culture and language scaffolds successful aging may be illustrated with the proverb study of Freund and Baltes (2002). Proverbs reflect culturally proliferated thumb rules on successful life management. Some of the proverbs were identified as reflecting adaptive life management strategies (e.g., 'a rolling stone gathers no moss'; 'the early bird catches the worm'), while other proverbs were more neutral in this sense (e.g., 'out of sight, out of mind'). Consistent with the expectation, people of all ages preferred proverbs that were identified as capturing adaptive life management strategies. Thus, the study underscores that on the cultural level individuals appear to be provided with functional knowledge on successful aging as embedded in social norms.

Another example illustrates individual efforts in creating the best possible positive match with existing resources, desires and needs, and adapting to certain contextual constraints. In her classical observation studies in the context of nursing homes, Margret Baltes (1996) reported a dependency-support script: According to these classic findings, nursing home staff reinforced dependent behavior while generally ignoring independent behavior of residents. Consequently, nursing home residents were found to behave more depending on staff, and less competent, which increased the likelihood of obtaining attention and contact of staff. After a retraining of nursing home staff to better acknowledge independent behaviors, this pattern was reversed (Baltes et al., 1994). Such findings also serve to illustrate that even late in life older adults have much adaptive competence for mastery of environmental demands. Again, such illustration from the nursing home context implies that successful aging may also be defined with regard to a standard of optimality.

How Does *Successful* Aging Differ from Normal and Pathological Aging?

A critical issue in research on successful aging pertains to the evaluation of patterns of stability or change in old age. There is much agreement that growth, stability, and decline may co-occur at the same time across different behavioral and psychological functions. For example, a person may experience a personal loss, while having stable self-esteem, and feeling even an increasing sense of control. The evaluation of successful aging may depend on functional (e.g., tests of everyday competence) or on statistical norms (e.g., divergence from average). In this vein, a critical issue pertains to discontinuity in age-related changes (e.g., Carlesimo et al., 1998). Discontinuity typically involves sudden changes, for example, related to a fall, a stroke, a loss, a failure, or an external event. In general, discontinuity in the

process of aging is more likely associated with undesirable or decline aspects of aging, whereas continuity or stability in the course of aging is more likely associated with positive aging (Gerstorf et al., 2006). The differentiation of successful to normal and pathological aging is strongly related to three fundamental aspects of the aging phenomenon, that is, (a) multidimensionality and multidirectionality, (b) the dynamics of gains and losses, and (c) plasticity (Baltes, 1987).

First, aging as a multidirectional and *multidimensional process* implies that success, stability, and pathology may alternate in time, and may even coexist within one individual across different domains of functioning (e.g., Morack et al., 2013). For instance, there is ample evidence that people can maintain high levels of life satisfaction and view themselves as successful agers even when facing chronic illness and age-related health impairments (Montross et al., 2006; Strawbridge et al., 2002). Multidimensionality reflects intraindividual differentiation across and within domains of functioning, while decline in the process of aging was observed to be associated with progressing dedifferentiation (Lindenberger and Baltes, 1997). It may be concluded that the observation of multidimensionality across adulthood is a critical premise for positive aging.

Second, life span psychology has put forth the understanding that there is *no gain without a loss*, and that there is no loss without a gain (Baltes, 1987). For example, advancement and progression often involve moving on and *away from* previous states (i.e., leaving behind something). Moreover, many investments in life (e.g., exercise, effort, acquiring new skills) imply that some of the invested resources (e.g., time, physiological functions) are depleted. And also, any loss may provide an opportunity for experiencing further personal growth (Baltes, 1987; Ryff, 1989). Thus, successful aging was defined as a balancing of gains and losses (Baltes and Carstensen, 1996). In this vein, studies demonstrate that the acknowledgment of meaning and personal growth is linked to positive outcomes (e.g., Levy et al., 2002 for the impact of positive aging perceptions; Zacher and Frese, 2011 for the work context). However, this notion involves that success may involve experiences of loss or failure. Here again, successful aging pertains to the standard of optimality, that is, a definition of what is the best possible adaptation in a given situation. For example, Ebner et al. (2006) were able to demonstrate that a switch in goal strivings may be functional across adulthood. In their study, young adults endorsed more growth-oriented goals (e.g., becoming healthy), whereas older adults rather preferred goals with a maintenance focus (e.g., staying healthy). Such age differences in goal focus were associated with well-being, and thus reflect an adaptation to the individual's available resources.

Third, aging entails much heterogeneity and malleability until very late in life. *Behavioral plasticity* refers to the flexibility of the self, as well as to cognitive and functional reserve capacities. This means that older individuals may be able to improve their abilities or even acquire a new skill even in the last years of life. In general, individuals are always capable to adapt to new environmental challenges. However, there also exist limits of such plasticity. While it is a robust finding that cognitive performance can be improved through training, it was also observed that there are age-associated limits in the best possible training performance (Baltes et al., 1995; Zinke et al., 2012). Furthermore, individual resources as well as contextual surroundings also enhance or hinder one's ability to act flexibly and proactively to age-related demands (Baltes and Lang, 1997; Lang et al., 2002). Plasticity (in its limits) may be seen as an important concomitant of successful aging, while the absence of plasticity points to less positive trajectories of aging. Consequently, behavioral plasticity constitutes, an important process characteristic of successful aging.

Together, multidimensionality, gain–loss dynamics, and behavioral plasticity point to the individual's potentials to co-organize and coconstruct positive aging processes within the boundaries of biological and cultural contexts. This conception of optimal aging builds on the idea that individuals are capable of intentional self-development and of proactive adaptation to changing life span contexts, which involves the question of what are the processes that contribute to successful aging.

What are Processes of Successful Aging? Selection, Optimization, and Compensation

Grounding on a wealth of theoretical and empirical findings regarding the potential and course of aging, Paul Baltes and Margret Baltes (1980, 1990) proposed the model of selection, optimization, and compensation (SOC) as a theoretical framework of successful aging. According to this model there are three interrelated developmental principles of behavioral adaptation and mastery in response to biocultural challenges in the aging process: *selection* as leading principle of behavioral choice, *optimization* as principle of enhancement and refinement, and *compensation* as principle of counterbalancing any kind of loss. In a first publication on this model, Baltes and Baltes (1980) introduced the model of SOC as follows: "*The adaptive task […] for the aging individual is to select and concentrate on those domains which are of high priority and involve a convergence of environmental demands, individual motivations and skills, and biological capacity*" (p. 59). In their work, Margret and Paul Baltes together with their colleagues have provided ample evidence that the processes of SOC contribute to proactivity and improved person–environment fit in later adulthood.

For each of the three adaptive processes the model assumes contextual conditions that may activate the respective behavioral mechanism. **Table 1** gives an overview on the contextual conditions, definitions, and involved behavioral processes involved in each of the three principles of SOC. In the following we shortly describe each of the three principles, and give empirical illustrations for how such successful aging principles may contribute to positive aging outcomes.

Selection encompasses strategies that aim at the reduction of and at focusing on personal meaningful goals or behavioral domains. At the same time, selection implies turning away one's efforts or behavioral resources from alternatives. This may include an adaption of goals, or an investment in new goals. Selection occurs in response to three premises of the life course: (1) opportunity structures provide options for differing individual pathways, (2) remaining time in life is limited, and (3) behavioral resources are exhaustible (e.g., health, mobility, cognitive performance). Two modes of the mental organization

Table 1 Definition, preconditions, and behavioral processes of selection, optimization, and compensation

Principle	*Contextual precondition*	*Definition*	*Behavioral process*	*Illustrations*
Selection	● Limitation of resources ● Finitude of life time ● Opportunity structures	Canalization of pathways and trajectories Emergence of opportunity structures	Mental organization of choices (tasks or goals); in response to loss (*loss-based S.*) or to positive events or outcomes (*elective S.*)	Giving direction to efforts or investments, commitment, abandonment, renewal of goals.
Optimization	● Amendability of resources ● Efficiency of resources ● Plasticity	Improving the function of a system or organism	Enhancing, refining, or strengthening a behavioral function (i.e., resources required for cognitive or physical activity)	Exercise, timing of activity, increased effort, cognitive motor control, solicit advice, generate information or new opportunities
Compensation	● Error-proneness (susceptibility to loss) ● Available, not used resources or opportunities	Replacing or restoring lost or failed functions Balancing failure or loss	Establishing new or restored behavioral functions in response to loss, limits, or failure (i.e., activating or using idle resources)	*Note: in response to anticipated future loss* (= *loss-based selection*), *In response to actual failure/loss*: Disengagement, motivation protection

(Eds.), Successful Aging: Perspectives from the Behavioral Sciences. Cambridge University Press, New York, NY, USA; Lang, F.R., Rohr, M.K., Williger, B., 2011. Modeling success in life-span psychology: the principles of selection, optimization, and compensation. In: Fingerman, K.L., Berg, C.A., Antonucci, T., Smith, J. (Eds.), Handbook of Lifespan Development. Springer, New York; and Marsiske, M., Lang, F.R., Baltes, P.B., Baltes, M.M., 1995. Selective optimization with compensation: life-span perspectives on successful human development. In: Dixon, R.A., Bäckman, L. (Eds.), Compensation for Psychological Defects and Declines: Managing Losses and Promoting Gains. Lawrence Erlbaum Associates.

of choices in life may be distinguished, that is, elective selection as a deliberate response to having options, and loss-based selection as a response to the limitation of resources.

Optimization captures efforts to enhance means and resources in order to reach one's desired goals. This process is highly dependent on the type and the amount of resources that an individual is able to invest. Clearly, optimization may also adhere to standards or norms of *optimality*, defined as a *best practice* in a given situation or context. Optimization pertains to those behavioral and contextual resources that are efficient, malleable, and amendable. As long as there is behavioral plasticity, individuals may refine, enhance, or strengthen positive aging outcomes. A debated issue in this vein is whether behavioral optimization requires goal pursuit or may also occur automatically (e.g., effortful activity without purpose; Lang et al., 2011).

Compensation occurs in the face of losses and constraints. It refers to the search and use of new means or resources that allow substitution of loss and therewith contribute to the stability or maintenance of performance. In line with the person–environment fit as criterion of successful aging two sources of compensatory efforts are possible, namely the increase of internal and external demands (cf Baltes and Baltes, 1990; Lang et al., 2011).

For instance, a person who notices memory problems may prefer to spend time in familiar contexts (selection), continue to invest in an active lifestyle (optimization), and use aids such as shopping lists (compensation). In the following we give a few notable empirical illustrations with regard to the social behavior, the pursuit of goals, and the use of technology in everyday life.

Empirical illustrations of SOC can be found in research on the formation of social relationships across adulthood (Lang, 2001). It is a robust finding that social networks tend to become smaller in old age. However, a closer look has revealed that such reduction of social networks was not just due to uncontrollable reasons such as increased immobility, health impairments, or the morbidity and mortality of social partners, but also reflects older adults' active attempts of matching resources, goals, and needs with contextual demands and challenges. More concretely, the reduction in network size is often restricted to peripheral social partners and acquaintances, but at the same time an increasing importance of close contacts and an intensification of family relationships is observable (Antonucci and Akiyama, 1987; Lang, 2001; Lang and Carstensen, 2002). Furthermore, individuals strive for positive social contacts, try to adapt social networks to their needs and resources, and proactively attempt to balance potential downsides and challenges of interpersonal relationships (Rohr and Lang, 2009). As mentioned earlier, the importance of long-lasting and close ties is increasing across life span and individual seek to maximize positive and emotional meaningful interactions (Birditt et al., 2005; Fredrickson and Carstensen, 1990; Lang, 2001). The enhancement of emotional needs in the regulation of one's social world is known to be associated with positive aging outcomes such as improved well-being (Lang and Schütze, 2002). Moreover, empirical research points to the benefits of social context for health and autonomy, physical activity, and for nutritional behavior (cf Rohr and Lang, 2009). In a series of studies, Levenson and colleagues demonstrated that older adults seem to be better in balancing relationship conflicts by using less escalating strategies, staying calmer, and expressing more affection to the partner (e.g., Carstensen et al., 1995; Levenson et al., 1993).

A second set of examples stems from research on the development of personal goals across the life span. In an impressive series of studies on the pursuit of goals across adulthood, Freund and her colleagues (e.g., Freund, 2006; Freund and Baltes, 2002; Freund et al., 2013; Riediger and

Freund, 2006) addressed the action-theoretical foundations of successful aging with regard to SOC. For example, Riediger and Freund (2006) explored whether similarity and ego-centrality of goals and the number of goals contributed to goal pursuit. Participants reported personal goals, which were rated for centrality (central vs marginal) and similarity (similar, belonging to one are of life vs dissimilar, spanning several life domains). Greater goal focus was positively associated with persistence and intensity of goal pursuit 3 months later. In another study (Freund, 2006), participants completed a sensorimotor working task in an optimization condition (i.e., improving performance, "try to get as good as possible"), or in a compensation condition (i.e., responding to loss, "try to get back to the level of performance in the first session"). Young adults were more persistent with the task in optimization instruction, while older adults spent more time on the task in the compensation condition.

Third, the model of SOC also contributes to improved understanding of how the use and adoption of technical solutions may improve successful aging outcomes. Based on the model of successful aging, Lindenberger et al. (2008) extracted three principles that enhance the usability of technical devices. First, technical solution should set free more resources than are needed for their use. Second, they should allow person-specific use, i.e., be adaptable to one's biography, needs, and competencies – and to individual changes in these aspects over time. Third, technological solutions should be assessed regarding their short-term and long-term benefits and risks. The aim should be that risks counteract benefits while the difficulty is to be aware of the principles of multidimensionality and plasticity. Melenhorst et al. (2006) underscore the importance of gain–loss dynamics for use of technical innovations in old age. In focus-groups, older adults aged 65–80 years reported to rely on anticipated gains in order to decide about using or not using a newly developed communication media device. In contrast, potential costs of use or nonuse seem less important in the selection and adoption process.

In general, research on successful aging puts forward the benefits of proactivity (e.g., Kahana et al., 2002; Klusmann et al., 2012). For instance, using longitudinal data from the Aging in Manitoba Study Menec (2003) showed that active engagement was linked to outcomes of successful aging such as happiness, life satisfaction, and physical functioning. However, each of these strategies goes along with chances and risks and functionality clearly depends on the person–environment fit. For instance, concentrating on a goal and dropping others (e.g., 'I want to stay mobile'), investing in a specific training (e.g., going to the gym), or choosing a certain way to reach one's goals (e.g., use of a wheeled walker) may also lead to potential misfits and failure (e.g., disease-related impairments such as hemiplegia, missing physical resources, being confronted with stairs in the house). Moreover, individuals who can draw on multiple resources such as sensorimotor and cognitive capabilities or social contacts did not only adapt better to age-related challenges, but were also able to delay functional losses by using strategies more efficiently (Baltes and Lang, 1997).

Conclusions and Outlook

Successful aging results from a fit between personal capacities and environmental demands. Individuals are proactive in selecting and shaping their environments in accordance with personal goals, needs, and capacities in order to obtain positive aging outcomes related to well-being and health. In line with this we proposed an *optimality* norm as a process-oriented criterion of successful aging.

The model of SOC includes three fundamental principles contributed to adaptive mastery and competence in the aging process. All together the model of SOC contributes importantly to improved understanding of how individuals may achieve successful aging outcomes even when being confronted with functional or personal loss experience. The principles of SOC were shown to be associated with improved functioning and strong well-being.

However, predictions of the model of SOC still lack further evidence from short- and long-term longitudinal data that empirically demonstrate the dynamic changes in the interplay of the three principles, and their impact on adaptation over time (cf Boker, 2013). Moreover, more research on cultural, societal, and historical influences on the processes of SOC is needed to better understand the contextual challenges in the aging process.

In all, the model of SOC serves to improve understanding of successful aging in a process perspective. SOC are ways through which individuals achieve improved and optimal person–environment fit in late, and thus contribute to positive aging outcomes in cognitive, behavioral, and emotional domains of functioning in later life.

Suicide

Thomas Bronisch, Max-Planck-Institute of Psychiatry, Munich, Germany

Abstract

The term suicide is used in the international scientific literature to avoid judgment as do terms like self-murder and voluntary death. Suicide belongs to the 10 most frequent causes of death among adults in industrialized European and North American countries. There is a considerable increase of suicides in societies with a high degree of secularization, industrialization, and individualization starting in the middle of the nineteenth century. The most important motive for suicidal behavior is certainly the impending loss of a human relationship, even if the wish to die outweighs the wish to survive in the suicidal act, i.e., in the seriousness of the suicide attempt. Biological studies could demonstrate a dysfunction of the serotonergic system in suicide victims and suicide attempters, which in psychopathological terms is correlated with a loss of impulse control, aggressiveness, affective instability, and violent suicide attempt. Empirical data about successful prevention of suicidal behavior is still lacking and successful therapeutic interventions only exist for subgroups of suicide attempters such as depressives with a treatment with lithium and mood stabilizers as well as cognitive behavioral therapy and psychodynamic psychotherapy for patients with borderline personality disorder.

Definition

The term suicide was mentioned for the first time in medieval times in 1177 (van Hooff, 1990) and comes from the Latin words *sui cidium* (self-killing) and *sui caedere* (to kill himself or herself). Now, this term is used in the international scientific literature. It avoids judgment, as do terms like 'self-murder' and 'voluntary death.'

In the realm of the term suicide, there are other terms that have to be defined. Suicide ideas include thinking about death either of one's own or someone else's or of death in general, the wish to die, and suicide ideas in a more narrow sense. It is not easy to define the term suicide attempt. The definition most commonly accepted is the following: "An act with nonfatal outcome, in which an individual deliberately indicates a non-habitual behavior that, without the intervention of others, will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognized therapeutic dosage, and which is aimed at realizing changes which the subject desired via the actual or expected physical consequences" (Platt et al., 1992). This definition includes an active intention for self-harm but not necessarily self-killing. Suicide and suicide attempt are also considered as suicidal behavior.

Importance of Suicide

Suicide belongs to the 10 most frequent causes of death among adults in industrialized European and North American countries. In these countries, suicide is considered the second most frequent cause of death among adolescents and young adults (15–35 years). Suicide in young male adults has increased constantly during the past 20 years. **Table 1** shows the frequencies of causes of death worldwide (WHO, 1999) disregarding the most frequent causes of death such as cardiovascular diseases, stroke, cancer, infectious diseases, and malnutrition. These figures have to be taken *cum grano salis* because of a dearth of inaccurate statistics on death in developing countries. As shown in **Table 1**, only fatal car accidents had a similar frequency of death as compared with suicide rates. War activities, crime, or even acquired immune deficiency syndrome at the beginning of the 1990s had a considerably lower death rate.

Epidemiology

The most recently available suicide rates from all over the world are depicted in **Figure 1** (see Schmidtke et al., 1999). This shows that a high variability of suicide rates exists across cultures and countries. Looking at the rank order of the frequency of suicide rates, a relatively stable pattern can be described – at least for European countries. There exists a North–South downgradient and an East–West downgradient of suicide rates: eastern and northern countries have higher suicide rates than western and southern countries. Hereby, sociological factors seem to play an important role in terms of secularization and industrialization with the collapse of the family group as a consequence as well as climate factors and genetic underpinnings, which cannot be disentangled sufficiently.

There exist distinct sex differences with a preponderance of males in suicide and a preponderance of females in suicide attempt. This distribution is stable across all countries and cultures. Only China reports a higher prevalence of suicide among women in selected areas.

The highest rate of suicide is found in people of older age and that of suicide attempt is found in younger people.

Table 1 WHO statistics: causes of death worldwide (1999)

856 000	*Death because of car accidents*
818 000	Death because of suicide
322 000	Death because of war
292 000	Death because of crime
291 000	Death because of acquired immune deficiency syndrome

Figure 1 Rank order of suicide rates (0–99+ years) of various countries. Reproduced from Schmidtke, A., Weinacker, B., Apter, A., Batt, A., Berman A., Bille-Brahe, U., Botsis, A., De Leo, D., Doneux, A., Goldney, R., Grad, O., Haring, C., Hawton, K., Hjelmeland, H., Kelleher, M., Kerkhof, A., Leenars, A., Lönnqvist, J., Michel, K., Ostamo, A., Salander-Renberg, E., Sayil, I., Takahashi, C., van Heeringen, C., Värnik, A., Wasserman, D., 1999. Suicide in the world: update. Archives Suicide Research 5, 81–89.

However, suicide occurring in children before prepuberty is very rare, but, without doubt, there is clinical evidence that children from 4 years of age have suicide ideas and can make a suicide attempt or kill themselves. Furthermore, it has to be taken into consideration that until prepuberty (8–10 years) children normally do not experience death as something irreversible (Pfeffer, 1986). Cultural differences exist in terms of using different suicide methods. The so-called weak suicide methods (ingestion of drugs, wrist cutting) and hard suicide methods (shooting, hanging, jumping, drowning, etc.) will be distinguished. Weak suicide methods prevail in suicide attempts, whereas hard methods prevail in successful suicide. In general, females more often prefer weak methods than males. The most frequent method for suicide in females and males in North America is shooting; in Europe, hanging; and in Asia, intoxicating with pesticides and rodenticides especially in rural areas.

Suicide rates in several European countries such as Germany, England and Wales, France, Hungary, and the Nordic countries show an astonishing stability over decades and even a century. The same holds true for German counties such as Saxony, Brandenburg, and Thuringia, where suicide rates have been stable over a century. Figure 2 depicts suicide rates over one century in Germany (Deutsches Reich and Germany (West and East), Felber, 2010). Such stability can even be traced (in other countries) back to the nineteenth century such as in Prussia, France, and the Nordic countries. On the other hand, there have been dramatic changes in suicide rates such as during the nineteenth century, where secularization, industrialization, and individualization have taken place in Western

Figure 2 Suicide rates per 100 000 inhabitants in the German Reich from 1900 to 1940 and in Germany (West and East) from 1945 to 2010. Reproduced from Felber, 2010.

and Northern European societies. During World Wars I and II, further dramatic changes occurred affecting not only males and females but also countries that have not been involved in these wars, such as Switzerland. Finally, the last changes have occurred after the fall of the Iron Curtain in Eastern Europe between 1985 and 1993 with a dramatic decrease in suicide rates by up to 40% and an increase after 1993 because of the economic, social, and political worsening in these countries (Mäkinen, 2000). However, the suicide rates are decreasing continuously again during the past 10 years because of amelioration of the economic, social, and political situation (Bronisch and Hegerl, 2010; *see* Mental Disorders, Epidemiology of).

Differing and Common Aspects between Suicide and Suicide Attempts

There are considerable differences between suicide attempters and suicide victims (Stengel, 1964). The latter group is rather small in comparison with the former group. The sociodemographic characteristics are quite different: suicide victims are older and predominantly male, whereas suicide attempters are younger and predominantly female. The tendency of a transition from the suicide attempters group to the suicide victims group is rather small with a 10% chance. The life of the victim is terminated by suicide, whereas a nonfatal suicide attempt becomes a very important event in the life of the person, often with a change in the further life trajectory.

Nevertheless, there are also some common aspects between these two groups: the probability of suicide is higher, the more often suicide attempts happen. Despite the fact that more males are committing suicide and more females make a suicide attempt, there is a considerable overlap between both groups. The same holds true for age distribution: a considerable proportion of young males and females commit suicide, while older males and females make suicide attempts. Most of the risk factors are equally valid for both suicide victims and suicide attempters (see below).

Risk Factors for Suicide and Suicide Attempts

Risk factors for suicide and suicide attempts are as follows: increased age; being separated, divorced, widowed, or single; unemployment; as well as gender and economical status (suicide occurs more often in males, suicide attempts occur more often in females and the lowest social class). The most important risk factors for suicide and suicide attempts, however, are a previous suicide attempt and a psychiatric disorder (Kreitman, 1977).

Gender

As already mentioned there is a higher suicide rate for males than for females. This seems to be surprising since the prevalence of depression is twice as high in females than in males (see below psychiatric diagnoses). This so-called gender paradox might be primarily based upon a preponderance of hard suicide methods in males as opposed to females, whereas in Asian countries such as China, the deadly intoxications with pesticides and rodenticides explain the preponderance of females (Möller-Leimkühler, 2003). Finally, a sociobiological explanation could be that women as guarantees for the transfer of genes from one generation to the other cannot afford suicide. This theory is backed by epidemiological data whereby females show the lowest suicide rates in all cultures and

societies depending on the number of children (Bronisch, 2007). Psychiatric hospitals bear a great risk of losing a patient to suicide. It has been estimated that 15% of depressed patients, 15% of patients with drug or alcohol addiction, and 10% of patients with schizophrenia, who have been treated in a psychiatric hospital, finally die by committing suicide. Patients with anxiety disorders or personality disorders also have a considerable risk of committing suicide. From an epidemiological point of view, subjects with a depression or an addiction have a 15- to 60-fold higher risk of committing suicide when compared with the general population (Bronisch and Hegerl, 2010).

There are differences between urban and rural areas with respect to suicide rates. The highest suicide rates are seen in urban areas, whereas the lowest rates are seen in rural areas. However, there are exceptions: the states of the former USSR as well as Asian countries such as China, where there is a preponderance of suicide rates in rural areas.

Climate also seems to play an important role in the distribution of suicide rates. The highest suicide rates are found during late spring and summer time. This distribution can be found across the Northern as well as the Southern Hemispheres. Countries in southern parts of Europe show a lower suicide rate than countries in the northern parts of Europe.

Religious affiliation also plays an important role in the frequency of suicides. In countries with a predominance of Catholics, suicide rates are lower, whereas in countries with a predominance of Protestants, suicide rates are higher. However, if the degree of urbanization and the distribution of social classes are taken into consideration, the differences between Catholic and Protestant countries are fading (Kreitman, 1977). The same holds for the Islamic countries where a rather low suicide rate can be observed (Okasha and Okasha, 2010).

Origins of Suicidal Behavior

Suicide as a Basic Human Existential Problem

Ever since the written history of mankind, suicide has been considered a basic human existential phenomenon that has been reflected in many philosophical and religious contributions as well as in all kinds of arts. The attitude toward suicide did not only depend on the *Zeitgeist* of the respective historical period but also on the individual stance of different philosophical schools such as of Stoa and Epikur in antiquity and different religions such as Christianity and Buddhism. The sociological theories are a consequence of the Enlightenment of the seventeenth and eighteenth centuries. During the first half of the nineteenth century, medical, especially psychiatric, explanations emerged and during the second half of the nineteenth century, psychological theories developed upon the influence of psychological thinking and emerging psychoanalysis. During the second half of the twentieth century, biological theories were finally stimulated by the natural sciences focusing on the brain.

Suicide requires self-reflecting properties of an individual, i.e., an individual who can differentiate between an observing and experiencing ego. Suicide does not exist in animals. Even nonhuman primates do not show suicidal behavior, neither in natural settings nor in preservations. However, suicide has been found in Neolithic societies.

Sociological Aspects

Durkheim's Theory

Sociological theories are influenced by the theory of Durkheim (1897[1951]) based upon the evaluation of suicide statistics of Western European countries (France and Prussia) during the second half of the nineteenth century. Durkheim proposed four different types of suicide depending on the degree of successful adaptation of the individual to different types of societies. A prerequisite to adaptation of the individual to society is that individualization is neither too weak nor too strong. If the individualization is too strong, the individual will be isolated from society and the danger of an egoistic suicide increases. If the individualization is too weak, the danger of an altruistic suicide increases.

On the other hand, a prerequisite to the equilibrium between the individual and society is that social norms are neither too strong nor too unspecific. Norms that are too strong facilitate fatalistic suicide such as an expiatory death. Norms that are too unspecific favor anomic suicide. With the help of the existing suicide statistics, Durkheim tried to verify three of the four types (he did not discuss the fatalistic suicide). He tried to prove that Protestant countries have a higher suicide rate than Catholic countries, since Protestantism allows the individual a higher degree of freedom than does Catholicism: it is called egoistic suicide. He explained the increase in suicide rates during political crises (Dreyfuss affair in France) in terms of an egoistic suicide. During times of flourishing economic growth, implying a derestriction of social norms, suicide rates should lead to an anomic suicide, whereas during times of war, stronger norms lead to a stronger coherence of society, resulting in a decrease in suicide rates.

General Sociological Trends

During the nineteenth century, only parts of Durkheim's theories could be confirmed such as the differences between Catholic and Protestant countries in Western Europe and the decrease of suicide rates during both World Wars. Generally speaking, Durkheim's data and statistical data from the twentieth century could demonstrate an increase in suicide in Europe during the nineteenth and twentieth centuries depending on the development of industrialization, secularization, and individualization of the respective countries, i.e., the more pronounced these developments were, the more frequently did suicide and suicide attempts occur (Retterstøl, 1992). Another quite remarkable trend of the past decades has been the increase in suicide rate of 15- to 35-year-old adolescents and young adults. In most Western societies, this development has been correlated with an increasing rate of depression and addiction potential. An increasing urbanization, loss of social structures and familial bonds, as well as changes in sex roles may play an important role in this development (Bronisch and Hegerl, 2010).

Psychological Aspects

Psychological models include psychodynamic, attachment, and cognitive behavioral theories that are only partially substantiated by empirical research. The main theories are

concerning the loss of a symbiotic relationship, and a severe personal insult resulting in severe loss of self-esteem. Finally, classical conditioning, operant conditioning, and model learning are, in terms of the behavioral point of view, also of great importance.

Aggression Directed against the Ego

S. Freud (1917) conceptualized one of the first psychological theories about the development of suicidal behavior in *Mourning and Melancholia*. To him, psychodynamics of suicidal behavior and depression were indistinguishable, i.e., suicidal behavior and depression were seen as a turn of aggression against the ego and an ambivalent attitude toward other people. Aggression directed against other people will be followed by loss of a desperately needed person. Turn of the aggression against the ego is expressed by feelings of guilt, self-devaluation, and finally self-killing.

Distorted Cognitive Schemes

Beck (1967) also emphasized a strong connection between suicidal behavior and depression. Depressive persons see themselves, the world, and the future (the so-called cognitive triad) negatively because of their distorted cognitive schemes. Catastrophization, minimizing, maximizing, and over-generalization belong to typically distorted cognitive schemes. As a consequence of such a cognitive triad, helplessness, hopelessness, and powerlessness result. In this case, the only solution for an individual may be to end his or her miserable life by committing suicide.

The entrapment in a vicious cycle of a negative evaluation of own coping strategies is been observed as an essential aspect of suicidal behavior in cognitive behavior theory (Williams, 2001). The result is a lack of development of distinctive problem-solving strategies. The basis for that is a deficient autobiographical memory for all kinds of life events, not only the positive but also the negative ones. A sufficient autobiographical memory is the basis of efficient judgment of future events. Suicidal persons are vague in regard to their future and therefore cannot develop effective problem-solving strategies. They do not know any solution, and experience the situation as hopeless and senseless so that suicide remains the only solution.

Narcissistic Crisis

Henseler (1974/1984) formulated the first narcissistic theory of suicidal behavior. Individuals with narcissistic personality traits are people who can be hurt easily by significant others through criticism or lack of special attention. They are lacking a stable self-esteem and their self-perception is distorted: they oscillate between overestimation and underestimation of their own abilities. This is not restricted to one's own character but also extends onto a corresponding distorted view of other people. Insults through criticism or lack of special attention lead to aggressive outbursts that can be directed either toward others or their own character in terms of a suicide or suicide attempt.

Appeal to Human Bonding

Attachment of the newborn to the mother is a characteristic common to all mammals. In all mammals, the newborn is very dependent and the reproductivity rate at least in the nonhuman and human primates is rather small. Therefore, the strong attachment is a life-preserving measure of the evolution to protect the dependent newborn until it is grown up. The emotional bonding in primates is very intense; separation of the mother will be experienced as very painful (Bowlby, 1977a,b).

As has been known from many empirical studies, most suicides and suicide attempts are consequences of imminent separation, separation, or divorce of males and females. The intention to die is ambivalent in most suicide attempts, i.e., besides a true tendency to end life in nearly all suicide attempts there are tendencies to survive. This can be seen easily in the choice of suicide methods, which often are not so dangerous, i.e., ingestion of small amounts of pills, or in the arrangement of suicide attempt that leaves a rescue open, i.e., by attempting suicide in the presence of a significant other.

The painfully expected or experienced separation from a significant other and the appeal of the significant others not to be left behind both seem to play an important role in the meaning of a suicide attempt (Bronisch, 2007).

Classical and Operant Conditioning

Basic principles of behavioral theory and therapy can be described using the Stimulus Organism Reaction Kontingency Consequence Scheme (SORKC scheme) of Kanfer (Schmidtke, 1988; see **Figure 3**). The SORKC scheme tries to describe each behavior in a broader context of conditions, which can be placed linearly in a chain or circle. The constituents of the SORKC scheme for suicidal behavior are the following:

1. Life events and social situations as Stimuli variables (S), which may trigger suicidal behavior.
2. Behavioral repertoire based upon organic conditions of the individual such as psychiatric disorders and the personality (e.g., cognitive styles and stances) as Organism variable (O), which may predispose to suicidal behavior.
3. Suicidal behavior as a reaction (R) to the S and O variables.
4. Kontingency (K), i.e., the reinforcement conditions, which support or suppress suicidal behavior, and behavior according to a regular or irregular order of the consequences.
5. Consequences (C) in the sense of negative reinforcement (e.g., death) or positive reinforcement (attention of the environment) of suicidal behavior.

The process hereby is rather circular, i.e., consequences can again influence further suicidal behavior. This might be possible by changing the individual (O variable) and the surroundings (S variable).

Model Learning

Imitation of suicidal behavior is a new area in suicide research. The observation that suicidal behavior is running in certain families, cultures, and countries could be explained by genetic transmission, psychological conflicts, or model learning. In regard to model learning, three hypotheses have been proposed: the imitation hypothesis, the contagion hypothesis, and the suggestion hypothesis. All three hypotheses have in common that suicidal behavior of a model will be imitated, whereby predisposition of the individual (the so-called

Figure 3 The cognitive behavioral scheme for the development of suicidal behavior. Reproduced from Schmidtke, A., 1988. Verhaltenstheoretisches Erklärungsmodell Suizidalen Verhaltens. S. Roderer, Regensburg, Germany.

'presuicidal personality'), lack of social support in coping with life crises, and enduring social burden are the contributing factors. Furthermore, a high degree of social suggestibility of predisposed individuals plays an important role.

During the 1980 and the 1990s the influence of different media, such as books, newspapers, journals, television, and movies, on increasing suicide rates can be demonstrated (Phillips and Lesyna, 1995). Suicide victims have resembled the person portrayed by the respective media: there have been similarities between this person and the suicide victim in terms of age, gender, motives for the suicide, and the methods used for suicide. The increase of suicide rate was in temporal relationship to the reported suicide cases and was not compensated by a decrease in later time, i.e., these suicides were committed earlier than planned. Also very impressive are studies that demonstrate a decrease in suicide rates not only by changing the information toward being more informative and being less sensational but also by reducing information about suicide (Phillips and Lesyna, 1995). One example is the studies of railway suicides reported in newspapers, which could be reduced by cooperation with local newspapers to reduce and confine to nonsensational reports on this matter. Mass media including Internet play an ever more important role in model learning of suicidal behavior. However, they could be also used for interventions such as restricting information about suicide methods as well as promoting preventive measures. These preventive measures could provide information, offer help, as well as control suicide-glorifying information in web sites, etc. (Westerlund et al., 2009).

In a broader sense, traditions in different cultures and countries concerning either permissive or restrictive attitudes toward suicide can also be regarded as a form of model learning. These attitudes may be transferred over generations such as in Hungary where an extremely high suicide rate can be observed throughout an entire century.

Biological Aspects

During the nineteenth century, Esquirol (1838) was the first to observe that suicidal behavior ran in families and, therefore, postulated that suicidal behavior was a kind of mental illness. Family, twin, and adoption studies gave hints about suicidal behavior having a genetic component.

There is a familial burden due to suicide and suicide attempts (of suicide victims or suicide attempters as compared with subjects without suicide or suicide attempts). Separation of nature (heritage) and nurture (rearing) is not possible within family studies, but it is possible within twin and adoption studies. In twin studies, identical (identical genes) and fraternal twins (half of the genes are nonidentical as in sisters and brothers) are compared with regard to suicide or suicide attempts. The respective studies demonstrate a significantly higher frequency of suicide and suicide attempts in identical as compared with fraternal twins (Roy et al., 1991). In adoption studies, identical twins have been compared with each other, whereby one twin has been raised with his biological parents, while the other twin has been adopted right away after birth. Significantly fewer twins raised by their biological parents

developed suicidal behavior or committed suicide than twins who had been adopted following birth. Furthermore, within biological families, a significantly higher rate of suicides or suicide attempts was shown than within adoptive families of the respective identical twin. All these studies also demonstrate that suicidal behavior has to be seen apart from a specific psychiatric diagnosis, especially apart from a depressive illness. On the other hand, the distinctive feature that might be inherited may not be suicidal behavior as such but rather personality traits such as lack of impulse control or aggressiveness (Wender et al., 1986).

Modern biological research on suicidal behavior started with the investigation by the working group of Marie Asberg (1976) of suicidal and nonsuicidal depressive patients. The following results of Asberg and coworkers could be replicated in several studies (Mann and Currier, 2007):

1. Patients after a suicide attempt showed lower values of 5-hydroxyenodolacetic acid (5-HIAA), the degradation product of serotonin, in the cerebrospinal fluid (CSF) than the psychiatric controls.
2. Patients with 'hard' suicide attempt methods showed lower 5-HIAA values in the CSF than patients with soft methods.
3. Patients with a higher lethal risk of a suicide attempt also showed lower 5-HIAA values in the CSF than those with lower lethality of a suicide attempt.

These results are further corroborated by postmortem studies, neuroendocrine studies, and investigations in peripheral parameters such as platelets, whereby the phenotype is not suicidal behavior per se but impulsive aggressive behavior that could be directed inwardly or outwardly (Mann, 1998).

The second biological system that contributes to the biological underpinnings of suicidal behavior is the stress hormone system. Based upon the preclinical findings, the stress hormone system with the hypothalamic–hypophysis-adrenal axis enhances the deficit of the serotonergic system and leads therefore to impulsive aggressive behavior (Bronisch and Hegerl, 2010).

During the past 10–20 years, molecular genetic research prevailed with rather inconsistent results. In pooled data from multicenter studies as well as meta-analyses polymorphisms in the serotonergic genes seem to predispose primarily to the endophenotypes of suicidal behavior such as impulsivity, aggressiveness, irritability, and hopelessness (Bondy et al., 2006). Further research is directed to molecular genetic aspects of suicidal behavior beyond the serotonergic system (Rujescu et al., 2007).

Prevention

Prevention can be divided into primary, secondary, and tertiary prevention. With regard to primary prevention, the main focus implies a reduction of tendencies within the society that support suicidal tendencies. A verdict of suicidal behavior by means of social ostracizing or punishment has not been successful in reducing suicide rates in medieval and modern times (Minois, 1995). However, primary prevention also concerns the prevention of suicidal behavior by ameliorating life conditions in general and socioeconomic conditions in particular as well as effective treatment of psychiatric disorders. It also refers to a support of tolerance for individual lifestyles. Furthermore, the restricted approach to frequently used methods, such as guns for shooting, can be helpful. Primary prevention also implies the amelioration of power of resistance against suicidal tendencies in the individual. Education of lay people and professionals in detecting and treating suicidal persons could be the most effective strategies. Secondary and tertiary prevention provided by fellow citizens (e.g., Samaritans) or medical or psychological professional personnel means prevention of relapses in suicidal behavior or rehabilitation of patients with suicidal behavior. Empirical studies proving the effect of the above-mentioned preventive strategies are still lacking. Physician education in depression and treatment and restricting access to lethal methods have reduced suicide rates so far (Mann et al., 2005). There is now an emerging trend to develop national suicide prevention programs in several Western and Northern European countries.

Therapy

Therapy has to be divided into crisis intervention, with actual psychiatric-psychotherapeutic intervention; pharmacotherapy; and psychotherapy. Crisis intervention primarily means prevention of an imminent danger of suicide. Crisis intervention should provide care and protection to the individual, i.e., protection of life, since suicide attempts often require medical care such as admission to an internal intensive care unit for detoxification or a surgical intervention. Crisis intervention also includes immediate evaluation of still existing suicidal tendencies of the patient in order to make decisions for further preventive measures: admission to a closed psychiatric ward for relapse prevention or crisis intervention on an in- or outpatient basis. Crisis intervention also includes acute psychotherapy and pharmacotherapy of the patient. The most important determinant of the psychotherapy is hereby the development of a supportive relationship between the suicidal person and the therapist. The greater the time lapse between the suicide attempt and the help offered, the more often are suicidal people inclined to disregard this help. A supportive relationship means that the therapist is accepting the patient's 'cry for help' and is making a commitment trying to understand the patient; however, the therapist is not willing to accept the patient's decision to end his or her life as a form of reasonable problem solving. The therapist clarifies the triggering situation that has led to the suicide attempt. Together with the patient, the therapist tries to develop other strategies to resolve seemingly insoluble conflicts in the patient's life. Also, an important determinant of a successful intervention is the involvement of significant others of the patient as well as the social environment in general. Acute pharmacological intervention means primarily sedation of the patient in order to keep him or her from further suicidal behavior.

Psychotherapy means treatment of psychopathological states such as depression, dysfunctional behaviors like impulsiveness, or pathological personality traits such as low self-

esteem. It includes the classical types of psychotherapy, i.e., psychodynamic approaches and cognitive behavioral approaches. So far, empirical studies could only demonstrate efficacy for some groups of patients, such as patients with borderline personality disorders by cognitive behavioral and psychodynamic therapies (Bronisch, 2011).

Pharmacotherapy of suicidal behavior is primarily focused on the underlying psychiatric illness of the patient such as schizophrenia (antipsychotics), depressive disorders (antidepressants), anxiety disorders (anxiolytics), and addiction (drugs against withdrawal symptoms). However, during the 1990s drugs specifically targeting the typical characteristics of suicide attempters such as impulsiveness and aggressiveness seem to have been successful in reducing suicide and suicide attempts: lithium and mood stabilizers. Antidepressants reduce suicidality in association with reduction of depressive symptoms, and it is assumed that suicidal behavior is also reduced as a consequence (Möller, 2010).

Concluding Remarks

Suicide and suicide attempt are a behavior confined to human beings. They are rooted fundamentally in the human existence and have as a prerequisite self-reflecting properties of the individual, i.e., conscious acting with the consequence or the attempt to extinguish one's own existence.

The attempts to describe suicide and suicide attempt based on a single cause in only one dimension has been tried by Esquirol (1838) in biology, Durkheim (1897[1951]) in sociology, or Freud (1917) in psychology and seems to be inappropriate. Suicide and suicide attempt are multidetermined acts (Roy, 2000). However, the weighting of different aspects of suicide and suicide attempt seems to be rather difficult to explain, so that in the following, only a synopsis of the empirical findings will be given.

Suicide is lacking in animals and even in nonhuman primates. However, it has already been found in Neolithic societies as well as later on in the old Greek and Latin societies. Precise empirical data about suicide in different countries and cultures has been lacking up to the nineteenth century so that a description of the development of suicide from the antiquity via the medieval to modern times is impossible. However, there is a considerable increase of suicides in societies with a high degree of secularization, industrialization, and individualization starting in the middle of the nineteenth century. For individual countries, there is often a stability of suicide rates on a high or low level depending at least in Europe on the degree of industrialization, religious affiliation, and climate: northern countries with a high degree of industrialization, Protestant religious affiliation, and rather few sunny days have considerably higher suicide rates than southern countries with a low degree of industrialization, Catholic religious affiliation, and many sunny days. The differences could best be explained by human bonding as a protective factor, whereas climate could influence biological rhythms, hence triggering suicidal behavior.

In regard to sex differences and suicidal behavior, very stable differences exist between males and females with a male preponderance in suicide and female preponderance in suicide attempts. The reasons for these sex differences, which seem to be stable across countries, cultures, and times, have not been well investigated and need further empirical research. There is no doubt that psychological motives play not only an important role as triggers for suicidal behavior but also are important determinants for the development of suicidal behavior. The most important motive for suicidal behavior is certainly the impending loss of a human relationship, even if the wish to die outweighs the wish to survive in the suicidal act, i.e., in the seriousness of the suicide attempt. Besides that, narcissistic personality traits predispose to suicidal behavior. From the cognitive behavioral point of view, classical conditioning, operant conditioning, and model learning are basic learning principles, which also can be transferred to behaviors such as suicide and suicide attempt. This way, model learning is not only important for perpetuating suicidal behavior in families and peer groups but also in societies with traditional high (Hungary) suicide rates (the so-called imitation hypothesis).

In certain families, a genetic burden of suicidal behavior could be confirmed by twin and adoption studies. This genetic burden is often connected to psychiatric illnesses such as depressive disorder, addiction, anxiety disorder, schizophrenia, and personality disorder. Biological studies (postmortem brain and peripheral biochemical studies) could demonstrate a dysfunction of the serotonergic system in suicide victims and suicide attempters, which in psychopathological terms is correlated to a loss of impulse control, aggressiveness, affective instability, and violent suicide attempt. These results are corroborated by molecular genetic studies.

As empirical studies could confirm, suicidal behavior is not a 'normal' behavior, but is rooted in psychological and biological abnormalities of the respondent with the corollary of prevention and therapy. However, empirical data about successful prevention of suicidal behavior is still scarce. Only physician education in depression and treatment and restricting access to lethal methods have reduced suicide rates so far. Successful therapeutic interventions only exist for subgroups of suicide attempters such as depressives with a successful treatment with lithium and mood stabilizers as well as cognitive behavioral and psychodynamic therapy for patients with borderline personality disorder. Life as a precious good, desperation and suffering of the respondents as well as suffering of the relatives should bring the focus on suicide more into the scientific scope of view as other life-threatening illnesses already have been for a long time.

Abstract

Suicide, the act of deliberately killing oneself, is shaped by a confluence of biological, psychological, social, economic, and cultural factors. When attempting to explain suicide, psychologists emphasize individual-level factors that are partly determined by biology, such as a history of mental illness or substance abuse. In contrast, sociologists recognize the important social aspects of suicide, focusing on variation in suicide at the aggregate level. Numerous cross-sectional and longitudinal studies provide support for the Durkheimian perspective that social integration and regulation, proxied by religious and demographic composition, family structure, and economic conditions, are associated with suicide rates. Contagion and access to means also play a role. A multidisciplinary approach to understanding suicide is required, integrating the micro and macro, social and psychological, and quantitative and qualitative approaches.

Definition and Measurement of Suicide

Suicide derives from the Latin word *sui* (of oneself) and *cide* (killing) and is defined by the World Health Organization as the act of deliberately killing oneself or intentional self-harm resulting in death. Historical accounting of suicide is fragmented but reveals substantial variation in our attitudes and beliefs about the act. Some in ancient Greece believed fervently in the right of an individual to choose the means and timing of death, and Eskimo and Norse cultures encouraged altruistic suicide among the elderly and sick. Yet Aristotle viewed suicide as an act of cowardice and a form of treason, the Romans prohibited suicide, and major religions imposed strong sanctions and prohibitions against the act (Jamison, 1999). Today, virtually all Western societies have decriminalized suicide, most recently Ireland in 1993, but attempted suicide remains a punishable offense in some countries and is an issue of debate among the US military (Dishneau, AP April 30, 2013). Although public understanding of the phenomenon has improved, considerable misinformation and stigma still surround the act.

Researchers often distinguish between completed suicide in which a death has occurred and other forms of suicidal behavior, such as attempts, suicidal ideation, and other types of self-harm such as excessive alcohol or drug use, promiscuity, or reckless driving. Completed suicides are widely believed to be underreported with estimates of the underreporting ranging from 10 to 50%. Underreporting is common largely because it can be difficult to ascertain intent since the majority of suicides do not leave notes or have witness reports. Measurement is also complicated by the fact that different areas may have varying legal and administrative procedures to report suicide. Moreover, relatives may apply pressure on coroners to avoid the stigma of suicide, although studies suggest the influence of this is marginal (Timmermans, 2005). Most researchers have concluded that suicide underreporting is randomly distributed and that official statistics can reasonably be used (Pescosolido and Mendelsohn, 1986). Still, caution should be used when making comparisons over geographic area and time due to potential differences in reporting practices.

Schools of Thought on the Etiology of Suicide

Historically, suicide was believed to be caused by supernatural forces or by an insufficient embrace of religion; by the 1500–1600s, the notion of insanity as a cause of suicide emerged. It is clear from current research that the etiology of suicide is complex, shaped by a confluence of biological, psychological, social, economic, and cultural factors that operate at both the individual and societal levels. Thus, the topic of suicide lies at the intersection of multiple disciplines, among them sociology, psychology, psychiatry, biology, public health, genetics, neuroscience, and philosophy.

Psychological and Biological Approaches to Understanding Suicide

Not surprisingly, psychological theories of suicide emphasize psychological pain as the root cause of suicide. The early psychiatrists, Sigmund Freud and Karl Menninger, asserted that three emotions – hate, depression, and guilt – characterize suicide and that these feelings give rise to an excessively critical superego and a wish to die. In the contemporary period, Edwin Shneidman's prominent 10-point definition of suicide emphasizes the intense 'psychache' experienced by suicide victims that leads them to view suicide as the only solution to their problems. Shneidman, the founder of the American Association of Suicidology, suggests that all suicides share 10 common characteristics, among them the need for a solution, unbearable psychological pain, hopelessness and helplessness, and a lifelong pattern of self-destruction (Maris et al., 2000).

As a result of this general theoretical framework, research coming out of the psychiatry/psychology fields focuses on the role of individual-level risk factors that are partly determined by biology, such as a history of mental illness or substance abuse. Using psychological autopsies in which data are collected through interviews and other sources about persons who have completed suicide, some studies indicate that close to 90% of individuals completing suicide suffered from some severe depressive disorder at the time of death. Twin and family studies show a strong genetic component to depression and

suicide, with current research estimating the genetic contribution to suicidal behavior somewhere between 30 and 50% (Joiner et al., 2005). Neurobiological work suggests that there are important serotonergic differences in depressed and suicidal individuals compared with others (see work by John Mann and colleagues), and some studies have linked the development and increased use of new antidepressants (selective serotonin reuptake inhibitors) to declines in suicide rates during the 1990s and early 2000s, particularly among the elderly (e.g., Gibbons et al., 2005). However, despite the clear significance of mental disorders in contributing to suicidal behavior, it remains the case that the vast majority of individuals who suffer from some mental illness do *not* commit suicide, suggesting the importance of other factors.

Individual-level analyses also reveal that a loss or lack of connection to others is an important underlying risk factor for suicide. Hopelessness has been identified as a significant correlate of suicide, along with other psychosocial factors such as burdensomeness, impulsivity and aggression, and ineffectiveness. These psychosocial factors may explain the strong links found at the individual level between (changes in) marital or employment status, physical or mental health problems, and substance abuse and the risk for suicide (Joiner et al., 2005; Maris et al., 2000). Psychologist Thomas Joiner interweaves these components in his influential interpersonal theory of suicide to identify conditions under which suicides are more likely to occur. According to Joiner's theory, suicides are more common when both the desire for suicide, spurred by feelings of social alienation and burdensomeness, and the ability to suicide, a fearlessness regarding death whereby one is capable of suicide due to prior exposure to life-threatening accidents or self-injurious behavior, coexist (Joiner, 2007).

Yet the psychological approach cannot effectively account for group-level differences in suicide risk, be they across geographic areas or different demographic groups. Nor can the individual-level approach explain other social aspects of suicide, such as contagion and the fact that suicide *rates*, a collective measure, may operate on a different explanatory level from individual suicides due to the effect of social interaction.

Sociological Approaches to Understanding Suicide

To address some of these limitations to psychiatric and psychological perspectives on suicide, sociological approaches tend to study suicide at the aggregate level to understand variation across groups. Sociologists' work on suicide is heavily influenced by Emile Durkheim, a founding father of sociology who argued that, although suicide is seemingly an individualistic act, it is also very much a function of a society's social structure – what he termed a 'social fact.' Thus, societal level characteristics, such as marriage rates, religious composition, and economic conditions, may produce variation in suicide rates, and a vast number of studies have tested Durkheim's ideas using data from a variety of countries and time periods. More recently, sociologists have introduced the notion of contagion in producing suicide as well as the role of networks. All these sociological approaches imply that social interaction is critical in affecting the well-being of societies and their members.

Durkheim's Original Thesis

In his book entitled *Suicide*, Durkheim examined patterns of suicide in nineteenth-century Europe, finding that some societies displayed higher suicide rates than others and that a country's suicide rate tended to correlate with other social characteristics. In explaining these patterns, he identified four types of suicide, which relate to levels of social integration and regulation within a society, as illustrated by **Figure 1**. Low levels of social integration within a society lead to instability and lack of cohesion, producing excessive individualism and high rates of *egoistic suicide*. Conversely, extreme levels of social integration can overwhelm individual needs, leading to *altruistic suicide*. A lack of social regulation produces anomie, an absence of norms and an inability of society to meet the population's needs and expectations, and corresponds to high rates of *anomic suicide*. Too much social regulation, on the other hand, in which individuals may feel oppressed, may produce *fatalistic suicide*, although Durkheim asserted that this is a rare form of suicide (Durkheim, 1951). Using this framework, Durkheim was able to explain why Protestant societies exhibited higher suicide rates than their Catholic counterparts and higher proportions of married persons are associated with lower suicide rate. He used the theory to predict that suicide rates would rise during periods of economic depression and boom as a result of rising anomie.

Critiques and Extensions of Durkheim

Durkheim's treatise has been criticized on a few grounds, most notably that he may have committed the ecological fallacy by drawing conclusions about individual behavior based on group-level statistics. Subsequent studies have found that differential recording practices across religious groups rather than differing levels of social integration and regulation may have accounted for some of the observed patterns (van Poppel and Day, 1996; but see van Tubergen et al., 2005). Others have

Figure 1 Durkheim's typology of suicide. Source: Marson, S.M., Powell, R.M., 2011. Suicide among elders: a Durkheimian proposal. International Journal of Ageing and Later Life 6 (1), 59–79.

noted that some typologies of suicide, namely, fatalistic and altruistic suicide, are not fully developed and that the distinction between anomie and egoism may be false (Johnson, 1965).

Jack Douglas (1967) in particular was highly critical of the Durkheimian approach in his book *The Social Meanings of Suicide*. His critique rests largely on the argument that suicide does not have a tidy definition – rather, it is a multidimensional and complex phenomenon. As a result, official statistics like death records or death certificates cannot reliably indicate the extent of suicide, as evidenced by the fact that coroners and medical examiners tend to underreport suicide and apply varying criteria to make the determination. Without a well-measured dependent variable, Douglas argues that quantitative approaches to suicide and their attempts to link the phenomenon to measures of social isolation or regulation should be abandoned. Instead, researchers should consider the subjective meaning of suicide by applying an ethnomethodological approach that focuses on the first-person accounts of actual suicidal individuals, namely, those who have made a prior serious attempt at suicide. Despite this criticism, it remains the case that the vast amount of sociological work on suicide is quantitative in nature.

Half a century after the publication of Durkheim's *Suicide*, Henry and Short (1954) revisited Durkheimian themes by examining how anomie and frustration can produce different types of aggressive responses. Like Durkheim, Henry and Short recognized the importance of external restraints (such as religion and particularly the economy) on suicide rates, but they introduced the notion of internal restraints (psychological components such as a strong conscience or propensity toward guilt) and the ways in which they may interact with varying levels of external restraints to produce different forms of aggression. Those experiencing weak external restraints (e.g., high social status and/or social isolation) and strong internal restraints (a well-developed superego) are more likely to take responsibility for frustration and internalize aggression (suicide) while those with strong external restraints and weak internal restraints are more likely to blame others for frustration and externalize their aggression (homicide). Although the theory is among the first to document the ways in which business cycles may affect social status and in turn levels of frustration and aggression, it has been criticized on empirical grounds since suicide rates tend to be higher among those of lower socioeconomic status; it cannot explain within-group variation in suicide/homicide rates and focuses primarily on level rather than change in status.

Gibbs and Martin (1964) expanded Durkheim's conceptualization of social integration by introducing the notion of status integration to explain societal-level variation in suicide rates. Individual behavior is largely governed by one's social identification or status, which carries with it a set of demands and expectations. An individual may occupy multiple social roles or statuses in the realm of family, work, community, and elsewhere. Status integration is determined by the degree to which the demands associated with one status are at odds with those dictated by another status; when roles are incompatible, social relationships are disrupted. Gibbs and Martin predicted that when a large proportion of the population faces a conflict in roles or lack of status integration, suicide rates rise. The authors pay close attention to the operationalization and advocate empirical testing of these concepts. Studies find support for the role of both occupational and marital integration in affecting levels of suicide (e.g., Gibbs, 2000).

Empirical Tests of the Durkheimian Perspective

Since Durkheim's original formulation, a large number of empirical studies have been conducted to determine the extent to which his theoretical framework is supported. Perhaps the earliest application to the United States following Durkheim emanated from the Chicago School of Sociology. Faris (1955) showed that socially disorganized neighborhoods in Chicago during the 1930s exhibited higher levels of social problems, including suicide and mental illness. These types of studies have proliferated in recent decades with the advent of large data sets and increased computer capabilities. The studies adopt both cross-sectional approaches, examining variation in suicide rates across countries or smaller geographic areas such as states or counties, and longitudinal designs, exploring factors that can explain variation in suicide rates over time within a given locale. Taken as a whole, the studies provide substantial support from many of the ideas put forward by Durkheim.

The Role of Religion

The role of religion in affecting suicide rates was central in Durkheim's argument. He presented evidence that Catholic societies exhibit lower suicide rates than their Protestant counterparts and attributed the difference to the degree of social integration and regulation present within the two Churches. While the Catholic Church is more communal and steeped in rituals with strong prohibitions against suicide, the Protestant Church, although prohibiting suicide, is more individualistic in orientation and places the responsibility for salvation on individual members. This tenet of Durkheim's *Suicide* – the idea that Catholics are more socially integrated and regulated and present lower suicide rates as a result – was once viewed as so infallible as to be coined sociology's 'one law' (Pope and Danigelis, 1981).

Recent research adds greater nuance to this finding, showing important differentiation by denomination. At the aggregate level, studies reveal that a greater proportion of more conservative Protestant faiths (such as Evangelical and Fundamental Christians) tend to protect against suicide while a greater prevalence of more liberal Protestant faiths (such as Mainline or Institutional Protestant churches) seem to raise suicide rates. The proportion of those adhering to Judaism tends to fall in between, having a small but protective effect (Pescosolido and Georgianna, 1989). A recent analysis of suicide rates across US states and over time between 1976 and 2000 showed that states with rising numbers of Catholics and greater declines in Episcopalians exhibited larger declines in suicide rates over the period (Phillips, 2013).

Contemporary work also offers insight into the mechanisms by which religious composition may affect suicide rates. The degree of religious heterogeneity appears to matter – an analysis of almost 300 metropolitan areas (MSAs) in the United States in 1979–81 revealed that MSAs with more homogeneous religious composition exhibit lower suicide rates, particularly in the Northeast and the South (Ellison et al., 1997).

Pescosolido (1990) attributes these differences to the strength of social networks – the more coadherents there are in an individual's direct environment, the more strongly involved and the greater support that individual will receive from the religious community, which in turn will lower the risk for suicide rate. van Tubergen et al. (2005) tested competing hypotheses about how and why religious communities (i.e., those with a high level of religious involvement) may be associated with lower suicide rates. Is the protective effect due to the fact that more religious communities and their social networks enhance the social and emotional support that their members experience, as Pescosolido (1990, 1994) proposes? Or do more religious communities impose stronger prohibitions against suicide than secular communities? Their study employs a rare multilevel analysis of suicide rates in the Netherlands to show that religious communities have a more general protective effect against suicide. As the proportion of religious individuals within a municipality increases, the risk of suicide declines within that municipality, regardless of an individual's own denomination and for non-Church members as well. These findings are consistent with the idea that a shared religious norm prohibiting suicide extends to all within the community and lowers the suicide risk, rather than the idea that social support from homogeneous others protects people from suicide.

The Role of Family Structure

Marital status and family are known to be among the strongest protective factors against suicide at both the individual and aggregate levels. Just as Durkheim observed in nineteenth-century Europe and explained using the idea of social integration, widowed and divorced individuals, men in particular, exhibit among the highest suicide rates while married individuals (over age 20 years) with children present the lowest rates. Of course, family relations are protective against suicide only when they are positive and strong. Evidence shows, not surprisingly, that family tension and conflict can elevate the risk of suicide at the individual level (Gibbs, 2000; Maris et al., 2000). For example, the risk of suicidal attempts among adolescents was reduced in families with higher levels of emotional and material support (forms of social integration) and with firm boundaries and greater parental supervision (Thorlindsson and Bjarnason, 1998).

At the aggregate level, research typically confirms that the higher the rate of divorce, the higher the rate of suicide, on average. This is particularly true for cross-sectional studies that examine variation across nations, states, and/or cities, but longitudinal studies that explore how changes in divorce over time are associated with changes in suicide rates often show a link as well. For example, Phillips (2013) found that US states with higher percentages of divorced persons exhibited higher firearm and nonfirearm suicide rates between 1976 and 2000, but that changes over the time period in the percentage divorced were positively associated only with nonfirearm suicide rates. Lester (1995) demonstrated that the divorce rate of a place is associated not only with the suicide rate of divorced people but also with those of the married, widowed, and single populations, suggesting that the divorce rate is a general indicator of the vitality of marriage as an institution and perhaps societal well-being.

The Role of the Economy

Durkheim hypothesized that suicide rates would rise during periods of economic depression *and* economic boom because both extremes can be viewed as indicators of anomie. With rapidly changing economic prospects in either direction, a society may be unable to adapt quickly enough to sufficiently meet its members' needs and expectations, weakening social regulation. Furthermore, the rise in unemployment during periods of economic recession has implications for social integration. Social integration may be undermined directly as unemployed individuals have more limited access to social support systems and indirectly because unemployment can produce relationship problems and/or financial difficulties that create stress, as well as harmful coping mechanisms, such as increased alcohol consumption. Studies show, for instance, an increase in excessive alcohol consumption during periods of economic downturn (Popovici and French, 2013). To test these assertions, research has adopted multiple measures of the economy, including unemployment rates, gross domestic product, real income, and sales, to determine its association with suicide rates.

Although cross-sectional analyses typically find limited support for a connection between economic conditions and suicide rates, longitudinal studies generally do find an association, supporting the more intuitive notion suggested by the Henry and Short model that suicide rates rise only during periods of economic recession (Stack, 2000a,b). One of the most comprehensive studies by Luo et al. (2011) examined business cycles and suicide rates in the United States between 1928 and 2007, showing that the total suicide rate tends to rise during periods of economic recession and fall during expansions. The study found some variation in the relationship by age group, with this association observed for those between the ages of 25 and 64 years, but no such relationship for those aged 15–24 years and over age 65 years. We might anticipate this variation by age, as those between the ages of 25 and 64 years are likely to be family breadwinners and supporting dependents and thus face greater hardship during periods of economic recession while the young and elderly are less likely to be in the labor force and often have the support of family and in the case of the elderly, social security. Although this analysis does not include the period of the 2009–10 Great Recession in the United States, US suicide rates have risen for those between the ages of 35 and 64 years during this period. A leading explanation for the recent spike among this particular age group relates to economic factors.

Studies using individual-level data confirm a powerful link between unemployment status and suicide risk (Maris et al., 2000). This relationship is particularly strong for men, who, historically at least, have been the family breadwinner with closer ties to work and careers than women and thus may experience more stress and feelings of failure when faced with unemployment. However, the pathways linking employment status to suicide at the individual level are less clear. While unemployment may increase suicide risk by creating financial strain, feelings of worthlessness, and relationship difficulties, it is also possible that those who possess a risk for suicide (e.g., through depression or substance abuse) may be more likely to become unemployed.

The Role of Social Stratification

Durkheim was relatively silent about the effect of social and economic stratification on suicide. He hypothesized that the poor would exhibit relatively low levels of suicide – essentially because he viewed poverty as a form of social regulation that protects against anomie during periods of recession. Henry and Short (1954) argued that the poor possessed strong familial and community relations but a disadvantaged social status, leading them to blame external factors for their difficulties. As a result, the poor were predicted to exhibit high homicide rates but low suicide rates. In reality, these predictions are not borne out by empirical data. The poor exhibit higher death rates from both homicide *and* suicide. Research on the effects of income inequality on suicide is limited and results are mixed, but scholars have explored race, gender, and life course disparities in suicide.

Race

Suicide rates are highest for Native Americans and whites and relatively low for Hispanics and blacks. Whites have rates three to four times those of blacks, a pattern that has remained remarkably stable over time. Scholars have put forward a number of explanations for the relatively low rates of suicide among blacks and Hispanics despite their economic disadvantage relative to whites. Some stress factors of social integration, such as the strong extended family networks and religious involvement within certain minority communities. Others note that suicide is highly stigmatized among the black community and viewed as 'a white thing' (Gibbs, 1997).

At the aggregate level, Kubrin et al. (2006) found that disadvantage (measured by factors such as male joblessness, poverty, educational attainment, and household structure) is associated positively with suicide for both young black and white men, but that industrial employment levels and changes therein as a result of deindustrialization are significant predictors of black male suicide rates only across US cities. Among Hispanics, higher levels of income inequality (relative to whites) are positively associated with suicide rates for the native-born but for foreign-born Hispanics, higher levels of black–Hispanic economic inequality are tied to lower suicide rates (Wadsworth and Kubrin, 2007).

Gender

With regard to gender, males are three to four times more likely to die by suicide than are females. Women, however, attempt suicide at higher rates but tend to use less lethal means such as poisoning, which are less likely to result in death. In terms of a sociological understanding of this differential, Durkheim, writing at the turn of the twentieth century, explained women's lower risk of death by suicide by suggesting that women are 'simpler social beings' with 'a less developed mental life.' As a result, women possess weaker ties to the collective and their behavior is not so heavily influenced by the social structure. Durkheim's arguments are now dismissed, and scholars today note that women may be protected from suicide because they tend to possess stronger and more frequent ties with family, friends, and community than do men and exhibit lower rates of alcohol abuse and higher rates of help seeking, among other explanations.

As women's status has changed over time, with increases in female labor force participation and divorce rates, one may expect to see changes in the sex suicide differential. Using data on 18 nations over a 40-year period, Pampel (1998) found that male and female suicide rates start to converge as changes in labor force participation and marital stability emerge. However, as women become increasingly involved in the labor force and institutions adjust, the female advantage in suicide reappears as their rates fall relative to men's, a pattern that occurs more quickly in collectivist societies. These findings are consistent with the conjectures of Gibbs and Martin, who argued that as status configurations (e.g., a married woman with children in the labor force) become more common, those in them may experience less role conflict and stress and lower suicide risk as a result.

Birth Cohorts

Demographers have focused attention on variation in suicide risk across birth cohorts or social generations. Cohort members share not only common contemporaneous but also historical sociocultural contexts that can influence behavior. Unlike prior work on suicide that tends to be divided along biological and social lines, the concept of a birth cohort implicitly connects biology and social structure by recognizing that the implications of a particular social or historical event can be distinct depending on the stage of life course at which that event occurs, with events during adolescence generally believed to be most formative in shaping attitudes and beliefs.

Most well known is Richard Easterlin's theory of relative cohort size in explaining variation in cohort behavior, which suggests that members of relatively large birth cohorts experience a number of social and economic disadvantages that persist throughout the life course (Easterlin, 1987). In childhood and adolescence, social integration and regulation are reduced due to factors such as large classroom size and reduced parental attention due to bigger average family size; in adulthood, members of large birth cohorts face greater competition in college and in the labor market. Age-period-cohort analyses of suicide rates find support for this theory, with cohorts of larger relative size and with a greater proportion of nonmarital births exhibiting higher suicide rates, net of age and period effects (Stockard and O'Brien, 2002a,b). Others have noted the possibility of a cohort-based argument for the unusual and marked increase in suicide rates between 1999 and 2010 in the United States among middle-aged baby boomers (Phillips et al., 2010).

The Theory of Contagion and Suicide Clusters

A contemporary of Emile Durkheim, Gabriel Tarde (1903 [1895]) introduced an alternative perspective on suicide in a book entitled *Laws of Imitation*, in which he proposed that individuals will imitate those behaviors and attitudes to which they are exposed in their social environment. The closer the proximity to those behaviors and the more frequent the exposure, the greater the likelihood of imitation. Although Durkheim largely dismissed the notion of imitation, historical and contemporary analyses of suicide rates over time or space reveal that suicides can occur more frequently or cluster in close temporal or geographic proximity. More contemporary versions of imitation theory or suicide contagion are known as the

'Werther effect,' named for the rise in suicides in 1774 following the publication of Goethe's novel about copycat suicides, whereby suicide rates may increase in the wake of well-publicized individual suicide cases. Simple awareness of a suicide act raises the possibility in the public's mind, akin to Joiner's notion of fearlessness. These ideas have been important in affecting guidelines for media reporting of suicide, which specify that details on method and location should not be included in public reports.

The sociologist David Phillips has been most influential in the recent period in promoting these ideas. Phillips (1974) demonstrated that coverage of celebrated suicides (such as Marilyn Monroe) on the front page of the *New York Times* newspaper was associated with a statistically significant increase in the national suicide rate 7–10 days after the publicity. The increase in suicide was greater the more extensive the front-page coverage and in geographic areas where the story ran. In another compelling study, Phillips (1982) tracked the association between the airing on television soap operas of fictional suicides and the actual suicide rate over a 10-year period, finding that the actual suicide rate spiked in the days following exposure to a soap opera suicide. Although the studies are suggestive of contagion, the ecological nature of the studies with minimal statistical controls limits our conclusions. However, research that includes more extensive controls for factors like unemployment shows more convincingly that contagion producing suicide clusters is more likely among teens and when the suicide involves a celebrity.

Suicide Prevention

While sociologists and psychologists have focused primarily on understanding the causes of suicide, public health practitioners are more likely to consider effective means of suicide prevention and postvention efforts. Historically, suicide prevention efforts rely on psychological approaches to understanding suicide and target those who possess well-known individual-level risk factors for suicide, such as a prior attempt or history of depression. Wray et al. (2011) lament the absence of sociological theories and explanations in suicide prevention research and call for a more active role moving forward, particularly in light of the expansion of community-based approaches to suicide prevention.

Perhaps the one exception to this individualistic approach to suicide prevention is the focus among public health scholars on the ways in which reducing access to lethal means of suicide can be a powerful prevention tool. This is most famously illustrated by the British Coal Gas story (Kreitman, 1976). During the 1950s, the British government began to move away from coal gas, which contained large quantities of carbon monoxide, and toward natural gas for domestic purposes. In the 10 years following this conversion, the national suicide rate declined markedly for all age–sex subgroups, sometimes by as much as one-third. The leading means of killing oneself – poisoning by gas inhalation – had been removed and suicides by other means increased only slightly, leading to an overall decline in suicide rates, particularly among females.

In the United States, Matthew Miller and colleagues at the Harvard School of Public Health have been most vocal recently in promoting the important role that means reduction must play in any comprehensive suicide prevention program (http://www.hsph.harvard.edu/means-matter). Research shows that a substantial number of suicide attempts are impulsive, that access to a lethal means, such as a firearm, is an important risk factor for suicide, and that individuals do not necessarily substitute an alternative method if access to a firearm is removed. For example, ecological studies show that for both sexes and all age groups in the United States, states with higher rates of household firearm ownership have higher suicide rates by firearm and overall, yet rates of nonfirearm suicide are not associated with gun ownership rates, indicating that displacement (from one method to another) does not occur (Miller et al., 2007). In sum, research shows importantly that any mechanism to slow down an action, whether requiring trigger locks on guns, placing barriers on bridges, or packaging pills individually, can be an effective way to prevent suicide.

Conclusion

A recent report by the Institute for Health Metrics and Evaluation on the Global Burden of Disease is a grim reminder of the importance of the topic. Worldwide, suicide was responsible in 2010 for more deaths than war, homicide, and natural disasters combined, and it was identified as the leading cause of death for those aged 15 to 49 years. Thousands of articles have been published on the topic of suicide, appearing in a wide variety of journals across multiple disciplines and underscoring both the complexity of and the continued interest in the mystery of suicide. Sociology has played a critical role in the understanding of the phenomenon, reminding us that even the most individualistic and intimate behaviors are products of the society we inhabit. Yet, as Wray et al. (2011) note in the *Annual Review of Sociology*, scholars are increasingly recognizing that a multidisciplinary approach to understanding suicide is required. Achieving that goal means that moving forward, sociologists must make concerted efforts to integrate the micro and the macro, the social and the psychological, and to employ both quantitative and qualitative methods in their quest to understand and ultimately prevent suicide (Wray et al., 2011).

Sumner, William (1840–1910)

Robert Bannister, Swarthmore, PA, USA

Abstract

The son of British immigrants, William Graham Sumner led a varied career as clergyman, social theorist, and sociologist. After studying at Yale, Göttingen, and Oxford, he was an Episcopalian minister from 1867 to 1872. Resigning his ministry, he was then professor of political and social science at Yale from 1872 to 1909. In numerous books and essays he championed free trade, sound money, and minimalist government. An anti-imperialist, he opposed the Spanish–American War (1898). His book *Folkways* (1906) coined the terms 'folkways' and 'mores'. Despite this important contribution to early American sociology, Sumner remains better known as America's leading social Darwinist.

Overview

Born in Paterson, New Jersey, William Graham Sumner (30 October 1840–12 April 1910), political economist and sociologist, was the son of Thomas and Sarah Graham Sumner, British immigrants who left their native Lancashire at a time when technological advances were rendering obsolete the skills of an entire generation of artisans.

From a background 'as humble as any', as he later described it, Sumner became one of Yale's most popular and influential professors, the author of a dozen books and some 150 articles in America's leading journals of opinion. A staunch anti-imperialist, he opposed the Spanish–American war of 1898. His *Folkways* (1906) added the terms 'folkways', 'mores', and 'in-group' to the sociological lexicon. In 1908–09, Sumner served as a president of the recently created American Sociological Association (ASA). His defense of individualism, free market capitalism, and limited government later earned him a reputation as America's leading social Darwinist, although this characterization has been contested.

Early Life

A less than happy childhood shaped Sumner's convictions and personality. A 'plain mechanic', as Sumner described his father, Thomas escaped the hard times of Lancashire only to fall victim to the American depression of 1837. Having trained himself to build and repair the sort of machinery that drove his own father into poverty, Thomas left Paterson after 5 years, traveling throughout Pennsylvania, Ohio, New York, and finally Connecticut in an unsuccessful search of employment.

Thomas's lack of formal education and his economic failures often set son against father. But his influence on William is difficult to overstate. William's causes echoed the aspirations and fears of Jacksonian era artisans – among them, antimonopoly, free trade, and a belief in the power of education. Although often characterized as an uncritical defender of industrial capitalism, William did not share his generation's faith in progress. When asked years later where he acquired his critical, scientific outlook, he credited his father. As he sorted out his deceased father's nonexistent estate, his estimate of Thomas grew, making him a model for the 'forgotten man', the tax paying, hard working, artisan hero of Sumner's What Social Classes Owe to Each Other (1884).

The death of Sumner's mother when he was eight, and his father's immediate remarriage, placed him in the care of a penny-pinching stepmother who was as stingy with affection as with worldly goods. Sumner disliked her intensely, at one point planning half-seriously how he and his younger brother Joe might kill her. He tempered his opinion when she encouraged his application to Yale, even trimming the family budget to provide him funds. Although she died before this largesse could be appreciated, the damage was done. Throughout his life Sumner built walls to contain emotion. On the surface he was all 'root, hog, or die', the sour-faced theology student who neighborhood boys taunted with shouts of 'Hey mister, why don't you smile'. Feelings for Sumner were personal, to be channeled, for example, into the adventure stories wrote in his early school years, his performances in college theatricals, love letters to his wife-to-be, and a surprising fondness of children – affection once desired but not received (Bannister, 1979, 1987, 1992; Bellomy, 1980; Curtis, 1981).

Education

Education was Sumner's salvation. Although some neighbors found 'little Willie Sumner' to be a conceited, overbearing prig, teachers in Hartford's North Grammar school remembered the perfect teacher's pet. Forced by finances to leave school for 2 years to work in a dry goods store, he was rescued by a Hartford clergyman named Elias Beadle, who guided him to Hartford High School's collegiate program. From there he entered Yale College, financed initially by family funds suddenly available thanks to Thomas's brief success in real estate, and later supplemented by aid from Skull and Bones classmates. This support eventually included purchase of a Civil War substitute, overseas studies, and a sabbatical when Sumner suffered an emotional collapse in the early 1890s (Bellomy, 1980).

As a Yale undergraduate (1859–63) Sumner followed the narrowly prescribed course laid out in the Yale Report of 1828: 2 years of the classics, drilled mechanically by young tutors, a third year that added some physics, chemistry, and

astronomy, and a fourth year where students got to hear lectures on history, politics, and law by Theodore Dwight Woolsey and Noah Porter, Yale's current and future presidents. Sumner's views on political economy, however, were acquired not at Yale, but earlier in a workman's institute library in Hartford. There he discovered Harriet Martineau's *Illustrations of Political Economy* (1832), an introduction for laymen to the theories of Malthus, Ricardo, and other classical economists through fictionalized accounts of mankind's efforts to wrest a living from nature. When Sumner later returned to these authors in the original, his favorite was Malthus, the bedrock of his thought in the later 1870s and 1880s.

While the Civil War raged at home, Sumner spent 2 years studying theology at the Universities of Geneva, Göttingen, and Oxford. Although each taught different lessons, a common thread was the impact of science, not just the much touted 'warfare of science and religion' but the nature of science itself. Despite some overlap, Sumner was exposed to three conflicting views. At Yale, and again at Oxford, science was a strictly inductive Baconian realism rooted in the Common Sense Scottish philosophy, which had dominated discourse in American colleges since early in the century. In teaching by example, Martineau effectively translated theoretical classical economics into the daily struggles of real men and women, stories to which laypersons could easily relate.

In Germany, Sumner dabbled briefly with the rationalistic Higher Criticism, an attempt to discover the meaning of biblical texts through literary and historical analysis. Oxford returned him to the common sense of Richard Hooker's *Of The Laws of Ecclesiastical Polity* (1894–97) and finally to Anglicanism.

At Oxford Sumner also had passing contact with a tradition of positivism going back to August Comte and now restated in Thomas Henry Buckle's *History of Civilization in England* (1865–66). So viewed, a science of history provided predictions based on a perceived regularity in human affairs, a probabilistic conception of natural law that later underlay the statistical sociology that gained popularity in the decades after Sumner's death. Although Sumner grappled with this view in his final years, he rejected it then just as he had ignored it in his Oxford year (Bannister, 1987).

Preacher to Scholar in Politics

In 1868, Sumner returned to Yale as a tutor in classics, combining it with service as Deacon in New Haven's Trinity Episcopal Church. The following spring (1869) he gave up tutoring to serve as assistant to the director of Cavalry Church, New York, and the editor of the newly launched publication, the Living Church. From 1870 to 1872 he was rector of the Church of the Redeemer in Morristown, New Jersey.

On 17 April 1871 Sumner married Jennie Elliot the daughter of a New York merchant. Reared to privilege, she found the role of professor's wife exhausting, falling victim to recurrent illnesses that made her a burden rather than partner. Sumner was nonetheless a loving husband and good father to their two sons, Eliot and Graham (Curtis, 1981). For Sumner, home life provided a welcome refuge from his professional duties, reinforcing the walls he built between feeling and facts. Sumner's presidential address to the ASA. in 1908 was a defense of the traditional family.

Although the first few years of their marriage were relatively happy, Sumner later recalled the 1870s as the worst time of his life. Anglicans were then divided between High and Low Church factions, the first concerned with tradition and ritual, the second tinged with an unacceptable evangelicalism ("Calvinist in doctrine, Methodistical in behavior", he wrote his wife-to-be) (Curtis, 1981). Sumner allied himself with the moderate Broad Church faction, serving as editor of their journal, the Living Church – living because it addressed current issues, church because it was an institution rooted in tradition.

Religious Views

Preaching to his Morristown parishioners, Sumner tackled issues that would concern him throughout his career. The enemy was rationalism which led to a solipsistic individualism and a sterile materialism, each the subject of sermons in the early 1870s. In surprisingly rare references to evolutionary theory and the threat science posed to religion, he also sought a middle ground: Huxley and Darwin were correct in 'their original works' (their method being the careful observation of facts) but not in the speculations others drew from their work. Likewise Sumner outlined a middle way between 'Tradition and Progress', the title of another of his weekly sermons.

Sumner never openly repudiated religion, perhaps mindful of his father's warning that Christianity should not be junked until humanity had something better to put in its place (Bellomy, 1980). After leaving the clergy he continued to attend weekly services, shocking a student who observed his tough-minded professor taking up collection at New Haven's Trinity Episcopal Church. By the late 1870s any religious fervor was gone. Sumner put his religious beliefs in a drawer, he later quipped, only to find 'nothing there at all' the next time he looked (Curtis, 1981).

Politics

Sumner made his transition from preacher to social theorist the hard way, through immersion in practical politics, locally and nationally. In 1872, he accepted a chair of political and social science at Yale, a position he held until his retirement in 1909. From this platform he launched a brief career as scholar-in politics, a term, being popularized by the Nation magazine. Locally, he joined the Young Yale movement to modernize the curriculum and increase alumni members of the Yale Corporation. He again sought a middle ground between radical demands to 'keep up with the times' and conservative defense of what he termed 'mere traditionalism and stagnation' (Bannister, 1992).

In 1873–77, Sumner served as a New Haven alderman. Joining the New Haven Chamber of Commerce, he undertook a crusade for free trade and sound currency, the subjects of *A History of American Currency* (1874) and *Lectures on the History of Protection* (1877). He served on the Finance Committee of the American Social Science Association, a forerunner of the ASA, only to resign in protest over its congenital reformism. In 1877, he joined an electoral commission to investigate fraud in the Hayes–Tilden

presidential election. The following year he testified before a Congressional Committee investigation of labor unrest.

The corruption in local and national politics left Sumner profoundly disillusioned. He concluded that he could do more harm than almost any man in politics because he did not know the rules and did not want to learn them. He declined to vote in the 1880 election and eventually supported the crusade for civil service reform. Joining the Mugwumps, he voted for Grover Cleveland in 1884 and 1888, but later found little to choose between the protectionist McKinley and the silverite Bryan. By the late 1870s his focus shifted from narrow partisan issues to broader social concerns (Bannister, 1992; Curtis, 1981).

Social Theorist

Several controversies in the late 1870s and early 1880s laid the basis for Sumner's reputation as America's leading Spencerian, and eventually as a social Darwinist who buttressed his arguments for a dog-eat-dog competition, private property, and laissez-faire with bogus analogies drawn from Darwinian biology. The first confrontation was with Yale President Noah Porter over Sumner's use of Spencer's Study of Sociology (1874) in a senior class in social science in 1878. Their battle, which soon went public, was one of several early attempts to defend academic freedom at a time when academics were establishing the legitimacy of still fragile disciplines. As with the theological battles of his Göttingen-Oxford years, the issue was not so much religion vs science but the definition of science. As Porter put it in his *The American College and the American Public* (1870) the issue was not whether the colleges would teach theology but whether it would be 'theology according to Comte and Spencer, or according to Bacon and Christ' (Heyl and Heyl, 1976).

Sumner at the time was indulging a new-found fondness of Spencer, whose *Social Statics* (1851) he had earlier dismissed as excessively metaphysical. During the 1870s, Spencerisms crept into his prose in references to 'first principles', the effects of 'action and reaction' and even 'progress … from the simple toward the complex', although not yet the tell-tale Darwinian phrases 'natural selection' and 'survival of the fittest', the latter a phrase Spencer himself used sparingly in his sociological writings after coining it in the early 1860s. The Porter crisis finally resolved itself when Sumner quietly dropped the Spencer text, and offered sociology only to graduate students while giving top billing to anthropology, a discipline longer on facts than on speculative analogies.

That might have been the end of it had Sumner not indulged some unmistakable Darwinian flourishes in his escalating battles against socialism and other radical reforms. In an article 'Socialism' in Scribner's (1878) he based his argument almost entirely on the works of Thomas Malthus, soon to be the target of Single Taxer Henry George in *Progress and Poverty* (1879). Sumner then charged that George 'wasted … effort' because 'the Malthusian law is swallowed up in a great biological law' – an apparent allusion to evolutionary theory. In a speech in the Free Trade Club that same year, and in several published and unpublished pieces over the next half decade, Sumner went a step further. "The law of the survival of the fittest was not made by man," he wrote in probably his best-known statements. "We can only, by interfering with it, produce the survival of the unfittest" (Bannister, 1979).

Seemingly unaware that he had stepped on a third rail of Gilded Age discourse, Sumner soon faced a firestorm. *The New York Times*, in an editorial titled 'The Selfish Sciences' condemned his 'lame analogy'. A member of the Nineteenth Century Club called it 'the baldest of bald truisms'. Even the Nation, which shared many of Sumner's views, commented that his way of expressing himself was 'occasionally unfortunate'. Sumner never recanted, although he tacitly admitted that he had crossed the line. His grasp of sociology was weak, he confessed. All he could 'affirm with certainty' was that social laws were 'in their entire character like the laws of physics'. Regarding struggle and survival, he sharpened a distinction between the 'competition of life' and 'the struggle for existence', the first being a social contest among individuals, subject to social rules and conventions, the second the collective struggle of humans against nature. The first could be altered, the second could not. Most social reformers confused the two, ascribing to the competition of life hardships due to the collective struggle with nature. Following a public exchange in 1884 on the issue of survival and fitness in the journal of the Free Religious Association, he dropped the fittest-unfittest epigram, never to repeat it again (Bannister, 1979).

The Forgotten Man

A new tone in Sumner's thinking appeared with the publication of *What Social Classes Owe to Each Other* (1884), next to *Folkways* his best-known book. Some readers then and later recoiled at his seemingly callous reduction of all humanitarian reforms to a school book logic wherein 'A and B decide what C shall do for D' – 'C' in this calculus being the forgotten man. What critics failed to note was the absence of any references to struggle, survival, or fitness. Instead he added a chapter 'Wherefore we should love one Another', a feel-good sermon designed to counter his 'unfortunate' way of expressing himself during the previous half decade. Also missing in the reviews was any note of the fact that Sumner had lost his appetite for cosmic laws and abstract rights.

Returning to the crude induction of Harriet Martineau's *Illustrations of Political Economy*, he now defined nature as the physical rocks and soil from which men wrested their living. Rights were nothing more than the freedom to pursue this activity without interference. Sumner's conception of science had always been a seesaw affair. While Baconian empiricism (induction) seemed the safest route, its dangers surfaced in the reform efforts of the social worker faction of the American Social Science Association as well as in the work of some representatives of the German Historical School of economics, the so-called Socialists of the Chair, both of whom abandoned theory for catalogs of social ills needing attention.

Sumner's forgotten man resurfaced almost four decades later when in one of his radio Fireside Chats (April 1932) Franklin Roosevelt appropriated the term, not to describe the hard working, tax-paying artisan Sumner had pictured, but the down-and-out victim of economic depression. Although a contributor to *The New York Times* (18 September 1932) attempted to set the record straight, the phrase soon entered popular culture in ways Sumner would not have recognized,

for example, in singer Joan Blondell's rendition of 'Remember my Forgotten Man' in Gold Diggers of 1933, as well as in several movies and a TV show. Year later he reappeared in Amity Shales' *The Forgotten Man* (2007), a critical account of the New Deal that drew acclaim in Tea Party and libertarian circles.

Farewell to Reform

In the late 1880s, Sumner's attention shifted from Henry George to Karl Marx and Edward Bellamy, author of the Utopian romance *Looking Backward* (1888), and also from free trade and civil service reform to plutocracy. Rejecting the metaphysical caste of reformers' appeals to liberty, rights, and equality, Sumner continued to provide crudely empirical translations of traditional liberal values. Liberty meant only the ability to gather the fruits of labor unimpeded by restraints. Liberty was inseparable from property, which in turn was the basis of liberty. Rights were measured by stuff you could see and touch.

This distinction was subtle but important. Historically the language of rights implied restraints on the powers of the state and escape from the past. In Sumner's translation, these terms validated the status quo. He adopted a similar tactic to cut through the haze of Marxian (and Hegelian) rhetoric. The proletariat was simply the 'House of Want', the state nothing more than 'all of us'.

'The Absurd Effort to Make the World Over' (1894) reflected this shift in method and mood. In place of logic or natural law, he answered social reformers with an 'appeal to the facts', historical facts in particular. "[All] the allegations of general mischief, social corruption, wrong, and evil in our society must be referred back to those who make them for particulars and specifications," he wrote. "That is why it is the greatest folly of which a man can be capable, to sit down with a slate and pencil to plan out a new social world." But had not Sumner himself devoted two decades to restoring America to the Republican virtues he inherited from his father? To this extent, as historian Donald Bellomy has noted, 'The Absurd Effort' was Sumner's personal farewell to reform.

Sumner's attack on plutocracy was more than a passing phase. As with many Mugwumps, he initially used the term to describe the vulgar nouveau riche, but by the later 1880s narrowed the definition to those who made money through politics, and in turn polluted politics with their money "[Plutocracy] is the thing which seems to me to be really new and really threatening," he wrote in one of three articles that appeared in the Independent in 1888–89. "There have been states in which there have been large plutocratic elements, but none in which wealth seemed to have such absorbing and controlling power as it threatens us" (Bannister, 1992).

Anti-Imperialist to Sociologist

During the 1890s, the power of money in politics was a centerpiece in his battle against imperialism and militarism. "The great foe of democracy now and in the near future is plutocracy…," he declared in 'The Conquest of the United States by Spain' a speech delivered on 16 January 1899 before a packed house in New Haven's old College Street Hall. "In that war militarism, expansion, and imperialism will all favor plutocracy." Spain's 'conquest' was in the realm of values, not on the battlefield. In pursuing overseas expansion the United States was adopting the values that had brought Spain to lowly estate. "My patriotism is of the kind which is outraged by the notion that the United States never was a great nation until in a petty three months' campaign it knocked to pieces a poor, decrepit, bankrupt old state like Spain," he concluded, in a line that drew applause from a previously skeptical audience.

Sumner's battle against militarism and imperialism had important consequences for his developing sociology. The disjuncture between America's professed intentions (spreading liberty) and the war's outcome (acquisition of the Philippines) dramatized the difference between purposes and consequences, the title of an unpublished essay written sometime after the turn of the century. "Motives and purposes are in the heart and brain of man," he wrote. "Consequences are in the world of fact".

During these years, Sumner discovered the work of Ludwig Gumplowicz and Gustav Ratzenhofer, representatives of the 'struggle school' of Austrian sociology. From them he learned the importance of warfare in the early stages of society although he preferred Gumplowicz's realpolitik to Ratzenhofer's ethical idealism. He also embraced the work of Austrian cultural historian Julius Lippert who stressed a historical view of traditions and the importance of group effort in the struggle for existence against nature, a process Sumner soon termed 'antagonistic cooperation'.

The growing gap between Sumner's beliefs and the imperialist bluster of modern America caught him between a system of values he could not accept but despaired of changing. With the Spanish–American war hero Theodore Roosevelt in the White House, America was entering its dangerous 'glory days'. The alternative of the silver-tongued William Jennings Bryan seemed even worse. He would vote for T.R., in 1908, Sumner wrote, but only "in order to ward off Bryan and Hades". His list of pet peeves grew by the day, finally including 'advertisers who exaggerate', journalistic excess, 'electioneering devices' and 'oratorical and dithyrambic extravagances in politics'. Although these things were not 'properly part of the mores they were symptoms of them', he added, using a term he coined in 1899 when he first began work on his science of society (Bannister, 1992).

Folkways

In *Folkways* (1906) Sumner poured his disillusion and growing pessimism into one of the most important books in early American sociology. In all societies people are driven by four basic instincts of hunger, love, vanity, and fear, he argued. Through trial and error, one method of satisfying these demands becomes customary for a significant part of a society. These folkways, as he called them, gain a moral sanction through comparison and reflection. The mores are folkways grown moral and reflective. Good and bad have no meaning outside of the mores. Mores that survive command the support of the most powerful groups. Thus 'nothing but might has ever made right', he added, using a phrase that drew fire from critics then and later. To complicate things Sumner acknowledged

that the mores could sometimes be wrong and 'positively harmful', a curious judgment if good and bad existed only within the mores.

His reply to this criticism was that an educated elite (the classes) had introduced the scientific outlook into the mores in the modern period. Using history as its laboratory, science could ascertain which mores were conducive to social survival. The mores that is, contained a self-correcting element. The distinction between an anterior and a posterior view explained why he was not advocating a might-is-right policy as often charged. Before the fact, the might that could be employed in no way determined the right of an action. A scientific view after the fact (posterior) proved the superiority of some values over others. Rather than being an enemy of tradition, as historically had been the case since the Enlightenment, science properly defined could be its best defense.

This resolution was not without its problems as Sumner at times appeared to advocate rule by a scientific elite of experts not that different from the 'sociocracy' that sociologist Lester Ward and many others were proposing. But Sumner's narrowly Baconian definition of the mores as facts – the other half of his reading of Darwin – translated into the view that the mores have a coercive character that transcends mere utility – a view similar to that of the French sociologist, Émile Durkheim. These facts did not rule out prudent change, but explained why it was folly to sit down with pen and paper and design a new world.

Sociological Legacy

Since Sumner died before his magnum opus *The Science of Society* (1927) was completed, the full scope and final direction of his sociology remains unknown. At Yale both sociology and graduate studies generally were poorly funded. Sumner had only six graduate students in sociology, four of them predominantly in social work. At least two of these students translated Sumner's teaching into proposals for government action he would have rejected: the socialist Henry Pratt Fairchild in calls for immigration restriction, eugenics, and birth control, and Frederick E. Lumley in *Means of Social Control* (1925). The later Cross-Cultural Survey in Yale's Institute of Human Relations owed a debt to Folkways but was more directly the work of anthropologist G.P. Murdock.

Reviews of Folkways were mixed. Some praised Sumner for putting sociology on a more scientific (objective) path. But even this praise was mingled with snide asides. Chicago sociologist George Vincent wrote that the ethnological data "seem at times to overweigh the book by their sheer bulk and multiplicity". Charles Ellwood, a Chicago PhD now professor at the University of Missouri, observed that the mores were not facts in the same sense as chairs and tables. "Whoever saw a tradition", he asked? Robert Park of Chicago, an advocate of a more objective sociology, said that Sumner's method 'if it can be called a method', consisted mostly of collection and description. Some refused to consider Sumner a sociologist at all. Vincent called him a folk psychologist. Albion Small, chair of Chicago's department, confessed that he never thought of Sumner as a sociologist until the Yale professor was elected president of the ASA (Bannister, 1987).

In the short run, Sumner's greatest influence was among several graduate students elsewhere. At Chicago, Luther Bernard drew directly on Folkways for his thesis 'An Objective Standard of Social Control', although like Sumner's own students he translated his sociology into a radical politics. At Columbia, F. Stuart Chapin, later the source of the widely used 'living room scales', wrote a thesis on Education and the Mores (1911). William F. Ogburn, later author of *Social Change* (1922) and the concept of cultural lag, used Sumner's work directly in a thesis on child labor legislation (1912). Franklin Giddings, chair at Columbia and one of the pioneers of American sociology, later called Sumner "perhaps the most consistently sociological if not the greatest of sociologists" (Bannister, 1987).

Despite their common dedication to objective sociology, the work of Ogburn, Chapin, and their many students differed from Folkways in being statistical rather than descriptive. In his thesis on child labor legislation, Ogburn charted existing laws statistically, defining 'best' as those closest to the norm, not by examining social mores regarding children and education. Like Sumner this new breed of statistical sociologist urged a more scientific approach to social problems. But, they generally supported Franklin Roosevelt's New Deal rather than the policies Sumner championed half a century earlier.

Sumner left no school of sociology, only a handful of disciples, mostly at Yale, and a book his biographer has described as an isolated masterpiece with no forebears or successors. However, the many references to mores and folkways in the scholarly literature of the past century reveal that his work has had wide-ranging if indirect influence outside as well as within sociology.

Social Darwinism

Sumner's contribution to sociology was soon eclipsed in the public mind by his reputation as America's premiere social Darwinist. Although this label as applied to Sumner has its roots in his rhetorical skirmishes in the early 1880s, it was Spencer who first earned the label 'le Darwinisme sociale' from European socialists, especially in response to his *Man versus the State* (1884). The term in its English translation 'social Darwinism' did not appear in the United States until the turn of the century, typically applied to a diverse group of thinkers who had little in common beyond their alleged misuse of Darwinism – eugenists, Nietzcheans, and German militarists heading the list (Bannister, 1979).

Until the 1940s the term social Darwinism rarely appeared in either scholarly literature or the popular press. This changed dramatically with the appearance of Richard Hofstadter's *Social Darwinism in American Thought* (1944). A brilliant tour deforce synthesizing more than five decades of debate over social applications of Darwinism, Hofstadter's book became one of the most influential works in American history. Although reviewers quibbled over his definitions, most praised his work. In their enthusiasm, however, no one noted that William Graham Sumner was included in the ranks of social Darwinists for the first time.

An exception was Sumner's student-turned-acolyte Albert G. Keller. "I find a scattering of social scientists as contrasted to social Darwinists on the Hofstadter roster," Keller wrote with Sumner in mind. "Some persons hopelessly allergic to 'isms' and 'ismics' have been ushered into the wrong pew". Ironically, Keller himself had contributed to Hofstadter's image of Sumner. During the years immediately preceding the publication of Folkways, he lectured Sumner on lessons to be learned from the Origin of Species, a work Keller himself first encountered in debates over neo-Darwinism in the 1890s. The first lesson concerned the importance of fact gathering, the second the role of struggle, selection, and transmission in the shaping of human cultures, a theme Keller later developed in his *Social Evolution* (1915) (Bannister, 1987; Smith, 1979; Smith and Hinkle, 1979).

Keller's celebration of facts was Baconian in the extreme. Fact gathering provided mental discipline formerly served by Yale's now defunct classical curriculum. Facts build character. With Darwin there was 'no sensitiveness about personal glory'. Facts were manly. "Lord knows there are enough 'It-Books', not to mention the 'She-Books'," Keller later wrote to sociologist Edward A. Ross. On this scale Sumner outdid even Spencer. "Spencer was something of an old maid and perhaps a little feline now and then," Keller reminisced. "But Sumner, with all his hard hitting … ought to appeal to anyone who, in these times, prays: 'O God, give us a Man!'" (Bannister, 1979).

Concerning facts, Sumner needed little persuasion. In more than 50 files boxes he collected thousands of note cards on traditions ranging from sports to incest. In Folkways he treated readers to a massive array of facts. But speculation based on analogies drawn from biology remained off-limits. For this every reason, he would not accept Keller's evolutionary view of the mores or his social selectionism. He underlined this point in a talk to Yale's Anthropology Club in 1905, although in deference to his mentor did not include these remarks in Folkways as originally intended.

Folkways were Darwinian only in the sense that it consisted of what Keller once termed a 'shovelfuls of facts', that is, hardly Darwinian in any recognizable sense. The word 'fittest' appeared only once with no reference to Darwin or biology. A chapter titled 'Societal Selection', described the triumph of some mores over others not in terms of struggle and survival of individuals or groups, but a subtler process he termed 'syncretism'. He continued to insist that the 'competition of life' and 'struggle for existence' were distinct albeit parallel phenomena.

Despite Keller's failure to convert Sumner to an evolutionist view of the mores, he did his best in later years to convey the impression that Sumner would eventually have capitulated. In a review of Folkways Keller stated that Sumner's book "constitutes a distinct and characteristic amplification of the evolutionary theory", adding that Sumner would agree.

In editing *The Challenge of Facts* (1914), the first of four volumes of Sumner's essays, Keller included several pieces emphasizing Sumner's debt to Darwin and Spencer. The first was a 'Sketch' of Sumner that appeared in the Spencerian journal Popular Science in 1889 based on Sumner's answers to a series of questions seemingly designed by the editors to show his familiarity with the work of Spencer and Darwin. The two others were previously unpublished manuscripts 'The Challenge of Facts' (originally 'Socialism') and 'The Predicament of Sociological Study'. As it happened, each included the epigram that the alternative to the 'survival of the fittest' was 'the survival of the unfittest', two of a handful of such comments in the early 1880s. Keller dated the first as sometime in the 1880s, and the second as after 1900s, leaving the impression that Sumner used such phraseology throughout his career. In Sumner's posthumous four-volume Study of Society, coauthor Keller gave the mores a Darwinian selectionist spin, echoing his own Societal Evolution (1915) (Bannister, 1987; Smith, 1979; Smith and Hinkle, 1979).

Keller's efforts paid off. "The fidelity of the work [Science of Society] to Sumner's major conceptions," Hofstadter wrote "is such that I have not hesitated to use it as a source". Writing in the journal Social Forces a few years later, sociologist Donald W. Calhoun agreed. "In evaluating Sumner's total contribution to the science of society, we shall follow these other commentators in treating the Science of Society as a source fundamentally parallel to Folkways and the essays".

Calhoun went on to praise the cosmic sweep of Sumner's investigations, his thoroughly sociological view of human society as embodied in the terms folkways, mores, and in-group, his divorce of value judgments from sociological inquiry, and his contribution to 'the behavioristic treatment of sociological data'. These points conceded, he then launched a blistering critique of Sumner's social views, capped by an attack on his social Darwinism (Calhoun, 1945).

A revisionist critique of the Hofstadter thesis first appeared in the early 1950s, initially in an analysis of the 'self-made man' ideology (Wyllie, 1959) and eventually as related to Sumner himself (Bannister, 1973; Bannister, 1979; Bellomy, 1984). Moderate revisionists argued that charges of social Darwinism misrepresented Darwin's influence on social thought in the Gilded age, Sumner in particular. Applied to society, Darwin's image of nature red in tooth and claw pictured a social order few if any Americans wished to defend in those terms. Scattered attempts to provide such a defense, met the vigorous opposition that greeted Sumner's rhetorical flourishes in the early 1880s. Portrayals of society in Darwinian terms were not intended to defend competition or laissez-faire but typically prefaced proposals that included the full range of progressive era reforms, including socialism, eugenics, immigration restriction, and Jim Crow racial restrictions.

A more extreme revision of the Hofstadter thesis argued that social Darwinists exist only in the minds of those who invented them, a socially constructed label with special appeal in a nation where almost half the population professes not to believe in Darwinism (Bannister, 1979; Bellomy, 1984).

While casting a shadow on his sociological legacy, a one-dimensional picture of Sumner as social Darwinist has also complicated efforts to place him in an American conservative tradition. In *The Conservative Mind* (1953), Russell Kirk, one of the leaders of the New Conservatism of the 1950s, pointedly excluded Sumner. More than a century after Sumner's death self-identified conservatives remain uneasy including him in the conservative canon. While opponents of the Tea Party have pictured the movement as heir to Sumner's social Darwinism (meaning a brutal, unfettered capitalism), many Tea Party supporters themselves sidestep Darwinism and instead embrace Sumner's views on the

importance of family or, alternately, see themselves as twenty-first century reincarnations of Sumner's forgotten men.

For some libertarians, Sumner's alleged use of Darwinism is itself the problem. If we can successfully distinguish evolution from liberty, one libertarian wrote, "we can save the Social Darwinists from themselves".

Historical revisionism has had limited success countering Sumner's reputation as dog-eat-dog social Darwinist. Some historians concede that Sumner and other conservative social Darwinists cited Darwin less than once believed. Others argue that Sumner is better termed a social Spencerian, a kinder, gentler social Darwinist. However, a Google/Lexis Nexis search of 'William Graham Sumner' and 'social Darwinism' tells another story, as hundreds of hits reveal that, in the public mind, Sumner is best known as America's leading social Darwinist (Hawkins).

Abstract

This article provides an overview of the risks of sun exposure and reviews the psychological literature on sun-tanning behavior, sun protection behavior, and skin cancer prevention. The different forms of skin cancer, their incidence, and causation are described briefly. The psychological predictors of sun exposure and sun protection behavior are reviewed. Finally, the effectiveness of skin cancer prevention programs is examined.

Sun exposure can be defined as the exposure of human beings to natural and artificial ultraviolet radiation (UVR). UVR emitted by the sun and devices such as tanning beds is a known human carcinogen (El Ghissassi et al., 2009). Accordingly, exposure to UVR is considered to be the main causal factor of all types of skin cancer (Armstrong, 2004). Appropriate sun protection behavior is an effective and essential means to prevent premature skin aging, as well as skin cancer at any age.

This article provides an overview of the incidence and causation of skin cancer, of the psychological determinants of sun exposure and sun protection behavior, and of different types of skin cancer prevention programs.

Skin Cancer: Incidence and Causation

There are two major classes of skin cancer: melanoma and nonmelanoma skin cancers (NMSC; subtypes: basal cell carcinoma (BCC), squamous cell carcinoma (SCC)). Three-fourths of all skin cancer-related deaths result from melanoma, indicating that melanoma is a more severe form of skin cancer than NMSC, which is often self-detected and successfully treated in doctor's surgeries.

Melanoma and NMSC Incidence

While the worldwide incidence rate of melanoma is lower than that of other types of cancer such as breast-, prostate-, and lung cancer, melanoma is the most common type of cancer diagnosed in Australian adolescents and young adults, accounting for more than 25% of all cancers in the age group between 15 and 29 years (Stiller, 2007). The age-standardized incidence rate for melanoma in Australia/New Zealand is 54.0 cases per 100 000, 19.7 cases in Northern America, and 11.7 cases in Europe, while incidence rates in Africa and Asia are much lower (0.9 and 0.3 cases per 100 000 respectively) (Ferlay et al., 2010).

Even though NMSC is a less severe type of skin cancer than melanoma, it is usually the most common form of cancer diagnosed in light-skinned populations, with incidence rates in some countries as high or higher as those for all other cancers combined. For example, in the annual report of the American Cancer Society (American Cancer Society, 2013), it is estimated that 3.5 million new cases of NMSC were diagnosed in the United States. This compares to a total number of 1.66 million annually diagnosed cancers across all body sites. Thus, NMSC constitutes a major burden in terms of both quality of life and treatment costs. As most national cancer registries do not routinely collect data on NMSC, it is difficult to obtain standardized estimates of worldwide incidence rates, especially for dark-skinned populations. A systematic review suggests a yearly increase of 5.5% in BCC across Europe (Lomas et al., 2012). The same study reported the highest worldwide incidence rate of BCC for Australia (ranging between 884 and 1813 per 100 000), while rates in Europe and Northern America ranged between 33.6 and 147.0 per 100 000. Rates of SCC are lower than those of BCC, ranging between 8.9 and 290 per 100 000 in Europe and Northern America, and between 387 and 1035 per 100 000 in Australia (Lomas et al., 2012). For both, BCC and SCC, incidence rates differ according to latitude, with more diagnosed cases of NMSC in light-skinned populations living closer to the equator.

Skin Cancer Risk Factors

There are several constitutional, environmental, and behavioral risk factors for skin cancer. Paler skin that burns easily, a personal or family history of skin cancer, and certain medical conditions that suppress the immune system are the most common constitutional factors. Additionally, atypical, numerous moles (i.e., more than 50) are risk factors for melanoma and there is an increased risk for NMSC developing on the sites of old scars or burns. UVR is the most important risk factor for any type of skin cancer (Armstrong, 2004). Thus, a history of excessive sun exposure, sunburns, and use of tanning booths increases the risk for skin cancer. Skin cancer sites and types vary according to exposure patterns and latitudes. Melanoma on less frequently exposed body sites is often associated with recreational sun exposure and sunburns across all latitudes, while melanoma on more exposed sites is associated with total lifetime and occupational sun exposure, especially at lower latitudes (Chang et al., 2009). NMSC is most

frequently found on commonly exposed body sites, such as ears, face, neck, and forearms. Studies suggest that childhood and recreational sun exposure is more related to BCC, whereas cumulative and occupational exposure mainly determines the risk for SCC (Armstrong, 2004). Sun exposure up until the age of 18 years seems to be causing the most critical damage with regard to cancer and premature skin aging; however, damage is still occurring in people aged 50 years and over (Kimlin and Guo, 2012). Overall, UVR was estimated to have caused the loss of 1.5 million disability-adjusted life years and 60 000 premature deaths in the year 2000 (Lucas et al., 2008).

There are three different types of radiation: UVA, UVB, and UVC radiation. UVC radiation does not play a role for the development of skin cancer, since it is blocked by the ozone layer. In the past, UVA radiation was thought to be less carcinogenic than UVB, since it induces less direct DNA damage. Recent studies, however, show that UVA is more carcinogenic than previously thought and that the basal layer of the skin is particularly vulnerable to UVA radiation (Agar et al., 2004). Therefore, many countries have introduced policies that require UVA protection labeling on sunscreens next to the sun protection factor (SPF), which only refers to UVB protection. UVR levels vary depending on season, time of day, latitude, cloud cover, altitude, and ground surface. The UV Index (UVI) is often reported in conjunction with weather forecast to alert the general public of the amount of harmful UVR on a particular day. The UVI is presented on a scale from 0 to 11+ and protection is required above the threshold value of 3 (Allinson et al., 2012).

Studies suggest that sun exposure is causing 99% of all NMSC and 95% of all melanoma (Armstrong, 2004). As skin cancer is a highly preventable disease, it is important to explore the factors influencing sun exposure and adequate sun protection measures.

Predictors of Sun Exposure

Sun exposure not only accompanies many occupational and recreational outdoor activities, it is often sought intentionally. One of the most important predictors of sun exposure is the desire for a suntan (Schüz and Eid, 2013). Even though the preference for tanned skin seems to be decreasing in countries such as Australia, where skin cancer awareness campaigns are well established, a significant proportion of light-skinned people are still actively seeking a tan because of a perceived increase in attractiveness (Stanton et al., 2004). Voluntary sun exposure is related to thinking more about one's physical appearance, to a higher fear of negative evaluations by others, and to a higher body self-consciousness and body self-esteem (Leary and Jones, 1993). Even though intention is usually a good predictor of behavior, appearance motivation seems to be a stronger predictor of sun exposure than the intention to avoid overexposure to the sun (Schüz and Eid, 2013). Next to the perception of improved appearance, relaxation also seems to play a role as a driver of UVR exposure. More than 76% of tanning bed users state that relaxation is a reason for tanning (Schneider et al., 2013). Moreover, when frequent tanners are given the choice between UV and non-UV tanning beds under blinded conditions, they are not only able to correctly distinguish between the conditions, but also actively seek UV exposure because of its relaxing effects (Feldman et al., 2004). In addition to appearance motivation and relaxation, sun tanning is related to a positive attitude toward risk-taking in general and to having friends who sunbathe and use tanning beds. Age and gender are important demographic predictors of sun exposure: Adolescents tend to spend more time in the sun than adults, and women report more deliberate tanning behavior than men (Stanton et al., 2004).

Predictors of Sun Protection Behavior

Deliberate sun exposure and the use of sun protection are two largely independent and only weakly correlated behaviors. Moreover, the predictors of sun protection behavior differ from the predictors of sun exposure. In contrast to sun exposure, appearance-oriented variables are less important for predicting sun protection.

The four most important sun protection behaviors are (1) avoiding direct sunlight, particularly during the peak hours of daylight (10 a.m.–4 p.m.), (2) seeking shade, (3) wearing a wide-brimmed hat, (4) wearing long-sleeved, dark clothing, and (5) using and reapplying sunscreen with an SPF of at least 15. These protective measures are endorsed whenever the UVI reaches a level of three or above. Additional recommendations include wearing sunglasses to avoid eye damage caused by UVR and tinting of car windows to block UVR. There have been some controversies regarding the effectiveness of sunscreen use for the prevention of skin cancer (Weinstock, 1999). However, studies show that adequate sunscreen use reduces the risk for both melanoma and SCC (Green et al., 2011). It has to be noted, however, that most people do not adhere to the usage guidelines for sunscreen and apply far less than what is recommended by manufacturers (around 35 ml per application), or do not reapply sunscreen regularly. Furthermore, sunscreen is often seen as a justification to overextend deliberate sun exposure (Stanton et al., 2004).

Even when awareness for the need of sun protection is high, many people do not adequately adhere to the recommendations, even in high-risk countries such as Australia (Stanton et al., 2004). There are several demographic predictors of sun protection: Women tend to report better sun protection than men, particularly with regard to sunscreen use. Light-skinned individuals protect themselves more than dark-skinned individuals, and adults report better protection levels than adolescents (Bränström et al., 2010).

Self-efficacy beliefs and perceived benefits and barriers of different sun protection behaviors are important sociocognitive predictors of sun protection, while many studies show that risk perception, operationalized as perceived vulnerability and/or severity of skin cancer, plays less of a role (Craciun et al., 2012b; Bränström et al., 2010). Sun protection self-efficacy beliefs pertain to a person's confidence that he or she is able to actually perform sun protection even in the face of difficulties (e.g., forgot to bring along sunscreen). There are both direct effects of self-efficacy on protection behavior and indirect effects mediated via sun protection intentions (Craciun et al.,

2012b). Commonly reported barriers for sunscreen use include the belief that sunscreen is greasy and sticky and the fact that sunscreen has to be applied repeatedly. Barriers against wearing hats are beliefs that hats are inconvenient to wear and cause problems with hairstyle. The major barriers against wearing shirts are the discomfort from heat and the feeling of being overdressed (Paul et al., 2008). Therefore, a goal of skin cancer prevention programs must be the removal of these specific barriers against sun protection behavior. Because these barriers partly depend on temporary fashion influences and differ between target groups, current and target group specific barriers of sun protection behaviors have to be explored before a prevention campaign is planned.

Social factors also have an important influence on sun protection. Use of sun protection is correlated with peers' sun protection behavior, parental influence, and parental sun protection behavior. Furthermore, people who know a person who has been diagnosed with skin cancer use sun protection more often (Leary and Jones, 1993).

To summarize, sun exposure and sun protection are two largely independent behaviors, influenced by a distinct set of determinants. While appearance motivation is an important predictor of sun exposure, self-efficacy beliefs and perceived benefits and barriers are more important drivers of sun protection. Moreover, behavior and beliefs differ according to sociodemographic group; thus, potential interventions may benefit from a targeted approach.

Skin Cancer Prevention

Interventions targeting sun exposure and sun protection behavior can take place on the population-, community- or individual level. Moreover, such interventions can focus on different aspects such as changes in policy (e.g., prohibiting the sale of sunscreen with an SPF under 30), education and communication (e.g., providing individual advice or making use of media campaigns), introducing technology (e.g., use of UV dosimeters to measure UVR), or providing people with resources (e.g., distributing free sunscreen). Due to the costs involved in appropriately evaluating different types of interventions, there is usually better evidence available for individual-oriented approaches than for population-based or community programs.

Examples of Population- and Community-Based Programs

The Australian SunSmart program is an example of a successful and well-evaluated mass-media campaign (for publications, see Relevant Websites). First introduced in 1988, more than 95% of the population is now familiar with its slogan Slip! (on a clothing) Slop! (on sunscreen) Slap! (on a hat). It is currently estimated that for every dollar spent on the program, $2.30 are saved in terms of cost for the health care system. The campaign aims to prevent 10 000 premature deaths, reduce melanoma incidence by 80 000 and NMSC incidence by 111 000 cases over the next 20 years (Shih et al., 2009). In conjunction with the SunSmart mass-media campaigns, sun protection in Australia is also enforced by policy: a study showed that 95% of childhood services reported to have a written sun protection policy which required all children to wear a hat and to use sunscreen (Ettridge et al., 2011). Moreover, having such a written sun protection policy is a requirement for accreditation of childcare centers. With regard to providing resources, a majority of Australian outdoor workers report that their employer provides them with sunscreen, protective clothing, and hats (Safe Work Australia, 2010).

The Pool Cool program is a successful and well-evaluated community-based program disseminated throughout the United States. With a theoretical basis in social cognitive theory, a main focus of the program is to provide people with sun protection skills, while taking into account environmental and structural changes, such as the availability of shaded areas and sun protection policies. The program was shown to increase sun protection among children and their parents, as well as to support the introduction of sun protection policies and environmental changes (for publications, see Relevant Websites).

More recently, smart phone applications that target sun protection behavior and skin cancer detection behavior have become available (e.g., the 'Solar Cell' app or the 'Know your skin' app). These provide real-time advice, e.g., via text messages, UVI forecasts, or educational and motivational messages, sometimes even tailored to the specific user. One prominent example is the 'Know your own skin' app that lets users take pictures of their moles and track potential changes over time by sending regular reminders to perform a skin self-check. Future evaluations of these types of intervention programs will show whether they are useful tools to prevent skin cancer.

Individual-Oriented Interventions

In contrast to population- and community-based programs, individual-oriented approaches to skin cancer prevention allow for better targeting of intervention contents. For example, as Schüz and Eid (2013) have shown, health-related time perspective (i.e., the extent to which future health is discounted over short-term outcomes such as getting a tan) is an important predictor of sun exposure intentions in adolescents, which can be successfully targeted in interventions. However, time perspective is less likely to play a role in adults, who are usually more aware of the future consequences of their behaviors as teenagers. Likewise, individuals who do not intend to use sun protection benefit more from an intervention involving resource communication, whereas motivated individuals profit more from an intervention involving planning when, where, and how to use sunscreen and how to face barriers toward sunscreen use (Craciun et al., 2012a).

In order to target appearance motivation, many interventions make use of UV photography. These are pictures taken under UV light that highlight damage to skin cells caused by UVR. Damaged areas appear as dark spots and are indicative of premature skin aging and higher risk for skin cancer. Some studies found UV photos to be effective in increasing sun

protection intentions and decreasing the use of tanning booth; however, the overall evidence for UV photos is inconclusive (Hollands et al., 2010). Moreover, messages that emphasize the negative effects of the sun on one's appearance can even lead to increased sun exposure intentions among individuals with high appearance motivation (Jones and Leary, 1994). This boomerang effect can be interpreted as a defensive reaction; messages highlighting the negative effects of tanning on appearance are challenging for individuals with a high appearance motivation, as they suggest that sun exposure has the opposite effect of what they want to achieve: it reduces their attractiveness rather than increasing it. However, a recent study has shown that an intervention combining UV photos with self-affirmation messages that enable individuals to process risk information less defensively reduces sun exposure among individuals with a high appearance motivation (Schüz et al., 2013).

Even though a range of evaluation studies on individual-oriented interventions targeting sun exposure and sun protection behavior is available, to date no comprehensive systematic review or *meta*-analysis exists that summarizes effective behavior change techniques in this area. However, a more general *meta*-analysis on health behavior change confirms the notion that tailored messages outperform more general health and risk messages, and that interventions addressing theory-based determinants of health behavior change are more effective than non-theory-based interventions (Noar et al., 2007).

Future Directions

Systematic reviews and *meta*-analyses summarizing the effects of interventions targeting sun exposure and sun protection behavior are needed in order to determine the effectiveness of different intervention components, thus providing much needed evidence for future intervention programs. A relatively recent field of research involves interventions using smart phone technology to target sun protection behavior. While this is a promising approach as smart phone applications are able to provide real-time advice in a tailored manner whenever the user asks for it, future evaluation studies are needed to prove the effectiveness of these applications. Moreover, future research will profit from the use of multimethod assessment strategies of behavior that does not only assess self-reported behavior but also uses observational and physical measures to validate self-reports (e.g., spectrophotometers for measuring the melanin skin content). As memory biases play a role when assessing sun protection and sun exposure via self-reports, ecological momentary assessment studies that assess behavior as it occurs in real time are a promising avenue for research on skin cancer prevention.

Supervision, Abusive

Christine MY Kermond, Michigan State University, East Lansing, MI, USA
John M Schaubroeck, The Eli Broad Graduate School of Management, Michigan State University, East Lansing, MI, USA

Abstract

This article summarizes research on abusive supervision in organizations. Abusive supervision refers to "subordinates' perceptions of the extent to which supervisors engage in the sustained display of hostile verbal and nonverbal behaviors". We review consequences of abusive supervision as well as the explanatory mechanisms of its relationship with these outcomes. We also discuss supervisor and subordinate factors contributing to abusive supervision perceptions. Finally, we review current methodological issues and describe promising future research directions.

Over the past two decades, the topic of abusive supervision has generated substantial interest in the popular press and among organizational scholars. Based on survey data reported by Schat et al. (2006), nearly 50% of employees in the United States have experienced abusive supervision in their working careers. One in seven employees reports that his or her current supervisor is abusive. Tepper et al. (2006) estimated that abusive supervision costs organizations $23.8 billion per annum. Since Tepper's (2000) seminal article that introduced the construct of abusive supervision, there have been over 100 journal articles published on the topic (Kermond et al., 2013a). Tepper defined abusive supervision as "subordinates' perceptions of the extent to which supervisors engage in the sustained display of hostile verbal and nonverbal behaviors, excluding physical contact" (p. 178). Examples of abusive supervisor behaviors include belittling and ridiculing subordinates, giving subordinates the silent treatment, making negative comments about subordinates to others, invading subordinates' privacy, and taking personal credit for the work of subordinates.

The purpose of this article is to provide a summary of the current state of knowledge about abusive supervision and to discuss emerging directions in theory and research. We organize our review in six sections: (1) Conceptual facets of abusive supervision, (2) Consequences of abusive supervision, (3) Mechanisms linking abusive supervision to outcomes, (4) Predictors of abusive supervision, (5) Methodological issues in abusive supervision research, and (6) Promising new directions in abusive supervision research.

Conceptual Facets of Abusive Supervision

Abusive supervision is usually examined in the context of a conventional supervisor–subordinate dyad, wherein the supervisory relationship is formal and position power is asymmetrical. It is conceptualized as a persistent and ongoing hostile behavioral pattern, meaning a one-time hostile outburst would not be considered abusive supervision. In addition, abusive supervision is an employee's subjective assessment of his or her supervisor's hostile behaviors toward him or her personally. Thus, the same behavior can potentially be perceived as abusive by one subordinate but not the other. Likewise the same behavior, for example, yelling, can be perceived to be abusive in one context (e.g., an office environment) but not abusive in another (e.g., a football coach directing players on the field).

Consequences of Abusive Supervision

Most abusive supervision research has focused its connections to individual victim's behavioral responses, attitudinal reactions, and personal well-being.

Work Behaviors and Attitudes

Aggression and Deviance

Victims of abusive supervision are often seen to engage in aggressive or deviant behaviors directed toward the supervisor, coworkers, and/or the organization (Mitchell and Ambrose, 2007). Meta-analyses have reported that on average, abusive supervision exhibits moderate relationships with deviant and counterproductive behaviors ($\rho = 0.39$, $k = 59$, $N = 19\ 700$; Kermond et al., 2013a; see also Schyns and Schilling, 2013). The relationship between perceptions of supervisory abuse and organization-directed retaliation was found to be stronger when the victim perceived that the organization is responsible for the abuse (Bowling and Michel, 2011). Tepper et al. (2008) observed that aggressive responses to abusive supervision were more likely to arise when the organizational context itself was perceived to be hostile, such as when coworkers condone deviance and engage in deviant acts themselves. Aggressive responses to abusive supervision also appear to be more prevalent when there is a hostile climate within a work group (Mawritz et al., 2012), or when there is a climate of uncertainty concerning the organization's leadership (Thau et al., 2009). Victims who intend to leave the organization were theorized to be less concerned with the repercussions of deviance, and thus are more likely to engage in retaliatory deviance against their supervisor (Tepper et al., 2009).

Performance and Prosocial Behaviors

Subordinates who report higher levels of abusive supervision tend to receive lower supervisory ratings of job performance

($\rho = -0.23$, $k = 14$, $N = 3185$; Kermond et al., 2013b; see also Schyns and Schilling, 2013). Abusive supervision victims are also less likely to engage in extra-role organizational citizenship behaviors in support of the organization (e.g., attend non-mandatory company functions, put in extra effort into work; $\rho = -0.23$, $k = 13$, $N = 2953$) or toward coworkers (e.g., adjust their work schedule to accommodate coworkers; $\rho = -0.20$, $k = 10$, $N = 2525$; Kermond et al., 2013b). Liu et al. (2012) reported that abusive supervision exhibited a stronger negative relationship with subordinates' creativity levels when subordinates attributed supervisory abuse to the supervisors' injurious motives rather than to performance-promotion motives.

Attitudes and Justice Perceptions

Abusive supervision is negatively related to subordinates' work and organization-related attitudes. For example, employees experiencing higher levels of supervisory abuse report lower job satisfaction ($\rho = -0.38$, $k = 24$, $N = 8953$), lower organizational commitment ($\rho = -0.21$, $k = 15$, $N = 4354$), and higher turnover intention ($\rho = 0.32$, $k = 21$, $N = 7982$; Kermond et al., 2013b; see also Schyns and Schilling, 2013). Abusive supervision is also negatively associated with perceptions of the supervisor's interpersonal justice practices (i.e., fairness of interpersonal treatment; $\rho = -0.61$, $k = 10$, $N = 2290$) and procedural fairness (i.e., fairness of procedures used to make allocation decisions; $\rho = -0.39$, $k = 6$, $N = 1658$; Kermond et al., 2013b; see also Schyns and Schilling, 2013).

Victim Personal and Family Well-Being

Psychological and Physical Health

Much research has examined the influence of abusive supervision on employee psychological and physical well-being. Evidence suggests that experiencing abusive supervision is psychologically draining for subordinates and impairs their capacity to self-regulate (Lian et al., 2012a). Abused employees often suffer from emotional exhaustion (Aryee et al., 2008). Victims of supervisory abuse also report higher levels of insomnia (Rafferty et al., 2010) and a greater tendency to self-medicate with alcohol (Bamberger and Bacharach, 2006). Meta-analyses report moderate correlations between abusive supervision and psychological distress ($\rho = 0.36$, $k = 40$, $N = 13\,330$; Kermond et al., 2013a; see also Schyns and Schilling, 2013), whereas relationships between abusive supervision and physical health symptoms are lower in magnitude ($\rho = 0.16$, $k = 10$, $N = 4662$; Kermond et al., 2013a). The strength of the relationship between abusive supervision and psychological distress appears to be more pronounced among subordinates with fewer job mobility options (Tepper, 2000). Abused employees also tend to be more depressed and anxious (Tepper, 2000).

Family

Individuals who report higher levels of abusive supervision tend to experience higher levels of conflict between their work and family demands (Tepper, 2000). They are also more inclined to take negative work emotions out on family members or domestic partners by exhibiting family-directed aggression (Hoobler and Brass, 2006). Similarly, Carlson et al. (2011) reported crossover effects of abusive supervision from work to family; higher levels of abuse were associated with greater relationship tension, lower family satisfaction, and more work-to-family conflict. A separate study found that subordinates' psychological distress explained the relationship between abusive supervision and subordinates' aggression toward their spouse or partner (Restubog et al., 2011).

Mechanisms Linking Abusive Supervision to Outcomes

A good deal of scholarly effort has been devoted to identifying explanatory mechanisms that link abusive supervision to adverse employee outcomes. Most theories of abusive supervision can be broadly distinguished between those that focus on relational mechanisms, such as exchange theories and other theories that concern perceptions of fairness, and theories that emphasize self-regulatory mechanisms.

Relational Theories

Relational theories as frameworks that describe how employees respond to abusive supervision based on inferences they draw from the abuse about their relationship with the supervisor and/or the organization. One such framework is fairness theory, in which judgments of fairness are driven by individuals' assignments of responsibility (Folger and Cropanzano, 2001). Uncertainty management theory highlights how being mistreated is especially important for employees who are uncertain about themselves or their relationship with the organization (Lind and Van den Bos, 2002). Social exchange theory describes the costs and benefits to employees of maintaining different forms of reciprocity-based relationships with their supervisor and the organization (Blau, 1964). Each of these theories has been invoked in studies highlighting fairness of some kind, such as supervisor interpersonal or procedural fairness, or in studying the influence of abusive supervision on the victim's level of trust in the supervisor. For example, an exchange perspective may highlight how abusive supervision elicits negative reciprocity, such that subordinates respond to negative supervisor treatment with negative behaviors (e.g., Peng et al., forthcoming). An uncertainty management or a fairness theory perspective may emphasize how being abused activates unfairness cognitions that confirm or disconfirm an existing schema about the organization, and this in turn influences the employee's motivation (e.g., Mayer et al., 2012; Thau et al., 2009). Below we highlight studies of abusive supervision that examined mediators that were consistent with one or more of these relational theories of abusive supervision.

Justice Perceptions

Tepper (2000) reported that overall justice perceptions partially mediated the relationship between abusive supervision and emotional exhaustion and anxiety. Aryee et al. (2007) demonstrated that abusive supervision elicits perceptions of interactional justice (i.e., the combination of interpersonal and informational fairness), which in turn influences subordinate organizational commitment and organizational citizenship behaviors. In a study reported by Burton and Hoobler (2011),

interactional justice mediated the relationship between abusive supervision and subordinate aggression. Zellars et al. (2002) reported that subordinates' procedural justice perceptions mediated the relationship between abusive supervision and subordinate organizational citizenship behaviors.

Leader–Member Exchange

Not surprisingly, abusive supervision appears to be associated with subordinate–supervisor relationships of poorer quality, in the organizational behavior literature leader-follower relationship quality is commonly operationalized by subordinate perceptions of the leader–member exchange relationship. Leader–member exchange quality refers to one's level of positive emotional connection to the supervisor, including affect-based trust and loyalty directed toward him or her (Scandura and Graen, 1984). When subordinates are in a poor exchange relationship, they are seen to withhold valuable exchange resources from the supervisor. Xu et al. (2012) reported that leader–member exchange quality fully mediated the relationship between abusive supervision and subordinate performance and organizational citizenship behaviors. Martinko et al. (2011) suggested that the relationship between abusive supervision and leader–member exchange may be less clear-cut, arguing that leader–member exchange might even be antecedent to abusive supervision rather than the reverse.

Attributing Blame to the Organization

Abused subordinates can indirectly reciprocate supervisor abuse by engaging in organization-directed deviance. Abusive supervisors may not only be viewed as representing the organization, many subordinates perceive them as embodying the organization (Eisenberger et al., 2010). Such employees may hold the organization responsible for the abuse and direct retributive actions against the organization. Shoss et al. (2013) examined the mediating role of perceived organizational support, defined as subordinate's perception that the organization values them and cares about their well-being. Their findings suggested that employees attributed their mistreatment partly to a lack of organizational support, and thus victims tended to engage in organization-directed deviance and withhold supportive extrarole contributions to the organization. Similarly, Tepper et al. (2008) reported results suggesting that abused subordinates also blamed the organization for the abuse, resulting in lower organizational commitment.

Emotions and Self-Regulation

Victims of abusive supervision may experience distinctly high levels of anger, fear, and/or anxiety (e.g., Rafferty et al., 2010; Tepper et al., 2009; Wu and Hu, 2009). Yet, because of the asymmetrical balance of power with the supervisor, abused subordinates may be deterred from directly confronting the supervisor or engaging in retributive actions against him or her. This can lead to pent-up aggression, which is often redirected toward more vulnerable targets. A displaced-aggression perspective (Dollard et al., 1939) is suggested by certain findings. For example, as noted above (Section Family), studies find that abusive supervision victims tend to experience a variety of troubling cross-over effects in their home life. These effects have been attributed in part to displaced aggression (Carlson et al., 2011; Hoobler and Brass, 2006).

The self-regulation impairment perspective argues that experiencing abusive supervision diminishes the victims' capacity for self-regulation (e.g., behaving normatively and rationally), because they are preoccupied with processing and interpreting the abusive events (Thau et al., 2007). Studies have reported that when abused subordinates had limited in self-regulatory capacities, as reflected in poorer impulse control (Lian et al., forthcoming-a; Thau and Mitchell, 2010) or uncertainty about their job competence (Mayer et al., 2012), they were more likely to respond to abuse by acting out in a counterproductive manner. Conversely, us of effective coping strategies appear to weaken the relationship between perceptions of abuse and subordinate deviance (Nandkeolyar et al., 2014).

Predictors of Abusive Supervision

Researchers have examined several antecedents of abusive supervision. The studied antecedents are primarily characteristics of supervisors and subordinates.

Supervisor Characteristics

Supervisor Traits

A small number of studies have examined relationships between supervisor traits such as authoritarian leadership style and supervisor Machiavellianism on abusive supervision. Subordinates who viewed their leader as adopting an authoritarian leadership style tended to also perceive higher levels of abusive supervision (Aryee et al., 2007). Authoritarian leadership style is defined as a "leader's behavior that asserts absolute authority and control over subordinates and demands unquestionable obedience from subordinates" (Cheng et al., 2004: p. 91). Supervisor Machiavellianism, which is the extent to which an individual manipulates and exploits others to maximize his or her self-interests (Christie et al., 1970), was positively related to supervisor authoritarian leadership style, which in turn predicted abusive supervision (Kiazad et al., 2010). Furthermore, subordinates with lower levels of organization-based self-esteem tend to perceive higher levels of abusive supervision when their supervisors exhibited an authoritarian leadership style (Kiazad et al., 2010).

Supervisors' Experience of Abusive Supervision

Just as abused subordinates may often displace their aggression onto individuals who are more vulnerable than the perpetrator of the abuse, supervisors may also displace the abuse they experience from their manager onto their own subordinates. Supervisors who perceive higher levels of procedural injustice (Tepper et al., 2006), interactional injustice (Hoobler and Hu, 2013; Rafferty et al., 2010), and psychological contract violations (Hoobler and Brass, 2006; Rafferty et al., 2010) are seen as more abusive by their subordinates. Abusive supervision can also 'trickle down' (or 'cascade' down) a chain of command. Abusive behaviors have been found to exhibit indirect effects

on abusive behaviors across two hierarchical levels, such that higher level manager abuse predicted lower level manager abuse (Liu et al., 2012; Mawritz et al., 2012).

In further support of the displaced-aggression hypothesis, Tepper et al. (2006) reported that supervisor depression mediated the relationship between procedural injustice perceptions and abusive behaviors. In addition, supervisors' conflicts with other supervisors at the same level were positively related to their subordinates' perceptions of abusive supervision (Harris et al., 2011). In addition, when supervisors' workplace stress levels were high, their direct reports reported significantly more abusive supervision (Burton et al., 2012). Finally, Kiewitz et al. (2012) drew upon social learning theory to explain how supervisor childhood experiences affect their abusive tendencies. They found that supervisors' experiences of family undermining (such as parent criticism, insults, unpleasant or angry treatment) during childhood were linked to their subordinates' reports of abusive supervision. This connection was weaker among supervisors with higher levels of impulse control.

Subordinate Characteristics

Subordinate Precipitating Factors

According to the victim precipitation model (Elias, 1986), targets of abuse often 'precipitate' abuse, meaning they indirectly or directly provoke the abuse. For example, abusive supervision victims may tend to be those individuals who are seen by the supervisor as the most vulnerable persons on whom they can release their own pent-up aggression. Victims may also provoke abuse because of their own negative dispositions, such as by behaving in a hostile manner toward others. A subordinate trait that is examined most frequently in this context is negative affectivity, which is characterized by frequent negative mood states such as feeling distressed, jittery, angry, depressed, or upset (Watson et al., 1988). Negative affectivity of subordinates has been linked to their reports of abusive supervision (e.g., Hoobler and Hu, 2013; Tepper et al., 2006), although it is uncertain whether this reflects the tendency of high-negative-affectivity individuals to provoke abuse or rather a general tendency of high-negative-affectivity individuals to interpret ambiguous stimuli in negative ways. Low job-related competence or low job performance quality may also make a subordinate more likely to become a victim of abusive supervision (Tepper et al., 2006).

Subordinate Attributions

Martinko et al. (2011) reported that employees with a hostile attribution style (i.e., attribute negative events to external and stable causes) perceived more abusive supervision than others, and that this relationship was mediated by perceptions of leader–member exchange quality. Subordinates' levels of psychological entitlement may also affect their attributions concerning their supervisor's abusive behaviors. Because psychologically entitled subordinates feel that they deserve high levels of praise irrespective of their performance or ability, compared to less psychologically entitled subordinates, they are more likely to perceive supervisor behaviors as being abusive (Harvey et al., 2014).

Methodological Issues in Abusive Supervision Research

Similar Constructs

In recent years, there has been a proliferation of constructs that conceptually overlap with abusive supervision. These constructs include petty tyranny (Ashforth, 1994), supervisor bullying (Fox and Stallworth, 2005), aversive leadership (e.g., Bligh et al., 2006; Pearce and Sims, 2002), supervisor social undermining (e.g., Duffy et al., 2002), supervisor verbal aggression (e.g., Chang and Lyons, 2012; Grandey et al., 2007), and supervisor incivility (e.g., Cortina et al., 2001; Leiter et al., 2011). See **Table 1** for the definitions of these constructs.

These constructs all refer to hostile and/or aggressive verbal or nonverbal behaviors directed by a supervisor toward a specific subordinate (Hershcovis, 2011). Scholars have raised concerns about construct proliferation in this domain, while also cautioning against ignoring key conceptual differences between the constructs, such as the intensity, intentionality, and perseverance of the abuse (e.g., Hershcovis, 2011; Tepper

Table 1 Definitions of constructs similar to abusive supervision

Supervisor abuse variable	*Definition*
Abusive supervision	"Abusive supervision refers to subordinates' perceptions of the extent to which supervisors engage in the sustained display of hostile verbal and nonverbal behaviors, excluding physical contact" (Tepper, 2000: p. 178).
Petty tyranny	A petty tyrant is defined as "an individual who lords his or her power over others … to overcontrol other and to treat them in an arbitrary, uncaring and punitive manner" (Ashforth, 1994: pp. 755–756).
Supervisor bullying	"A situation where one or several individuals persistently over a period of time perceive themselves to be on the receiving end of negative actions from one or several persons, in a situation where the target of bullying has difficulty in defending him or herself against these actions" (Einarsen and Skogstad, 1996: p. 191).
Aversive leadership	"Leadership that primarily relies on coercive power and is rooted in punishment" (Pearce and Sims, 2002: p. 173).
Supervisor social undermining	"Behavior intended to hinder, over time, the ability to establish and maintain positive interpersonal relationships, work-related success, and favorable reputation" (Duffy et al., 2002: p. 332).
Supervisor verbal aggression	"Verbal forms of aggression involve efforts to inflict harm on others through words rather than deeds" (Baron and Neuman, 1996: p. 163).
Supervisor incivility	"Workplace incivility is low-intensity deviant behavior with ambiguous intent to harm the target, in violation of workplace norms for mutual respect" (Andersson and Pearson, 1999: p. 457).

and Henle, 2011). Conversely, the metaconstruct of destructive leadership refers to generally undesirable characteristics or behaviors of leaders that are not necessarily targeted toward a specific subordinate (Einarsen et al., 2007; Padilla et al., 2007). Constructs included under the rubric of destructive leadership are distinct from those just mentioned because they refer to subordinates' perceptions of leader behaviors directed toward others in general, rather than toward a specific subordinate (e.g., despotic leadership; De Hoogh and Den Hartog, 2008), or to behaviors or traits that do not constitute abuse, per se, but which are seen as undesirable for other reasons (e.g., authoritarian leadership style, narcissistic supervision, negative leadership, psychopathic leadership; Schyns and Schilling, 2013).

Self-Reported Data and Cross-Sectional Research Designs

Abusive supervision researchers have mainly relied on variables measured at one time point or measured outcome variables at a separate point in time (e.g., staggering data collection over two to three periods). Many studies have relied exclusively on subordinates' self-reports about both their leaders' behaviors and the outcome variables. Because abusive supervision is conceptualized as a dyadic process, the potential benefits of aggregating perceptions across multiple subordinates of the same leaders in reducing common method variance are not realized. Thus, cross-sectional studies and studies that take little advantage of time separation or which do not focus on moderated relationships are prone to spurious inflation of studied relationships owing to common method variance. Among the few exceptions, Thau and Mitchell (2010: sample 3) employed a repeated measures design that measured abusive supervision and deviant behaviors over 10 time points. The authors found that the within-person relationship between abusive supervision and deviant behaviors was mediated by self-regulation impairment. Another example was provided by Lian et al. (forthcoming-b). They obtained repeated measures of abusive supervision and subordinate deviant behavior, measuring both variables at two time points. In one study in which the measures were separated by a 20-month lag, their cross-lagged analyses suggested that subordinate deviant behavior leads to abusive supervision rather than the reverse. A second study with a 6-month lag between repeated measures suggested a reciprocal relationship between subordinate deviant behavior and abusive supervision. They argued that the differences between the two studies in time lag explained the diverging results.

Inadequate Model Specification

Although there are a few exceptions (e.g., Aryee et al., 2007; Lian et al., 2012b; Peng et al., forthcoming), abusive supervision studies have tended to focus on one mediating variable at a time. Examining a single mediating pathway may not adequately reflect the various theoretical mechanisms responsible for the relationship between abusive supervision and employee outcomes. This is of particular concern in studies in which abusive supervision and the putative mediator are not separated in time and common method variance is a concern, as this can exaggerate the estimated sizes of indirect effects.

Promising New Directions in Abusive Supervision Research

In addition to promising trends in the direction of longitudinal designs and investigating multiple pathways of mediation as noted above, there are other positive trends in the way abusive supervision is studied and in the depth and scope of the research questions addressed. Researchers have moved toward examining the social context of abusive supervision, including investigations of the role of coworkers' abusive supervision levels in how individuals respond to their own experiences of abuse, testing multilevel processes related to abusive supervision, examining abusive supervision in non-Western cultural contexts and investigating cultural differences as moderator variables, and giving long-overdue empirical attention to means of preventing abusive supervision.

Third-Party Observers of Abusive Supervision

The deontic justice perspective suggests that observers of injustices inflicted on others experience outrage and often engage in retributive actions to punish the source of the injustice and aid the victims (e.g., Lotz et al., 2011; Turillo et al., 2002). A third-party observer may learn about the abuse of another individual through word of mouth from the abused employee or from other observers. If the observer deems the target of abuse as undeserving of the ill treatment, he or she may attempt to restore justice by lashing out to the supervisor, or report the abuse to a higher authority in the organization (Skarlicki and Kulik, 2005). Umphress et al. (2013) found that third-party observers displayed anger toward abusive supervisors and they reported an intention to take corrective or punitive response, especially when they perceived that the abuse was intended to harm the target employee.

Multilevel Research

Tepper (2007) called for more multilevel research on abusive supervision, noting that "abusive supervision is a multilevel phenomenon and the field needs to move beyond individual-level research" (p. 281). One approach to multilevel research on abusive supervision examines the interaction between subordinates' own reports of experiencing abusive supervision and the average group experience (i.e., average levels of abusive supervision as reported by work unit peers (i.e., 'work unit,' 'coworker,' or 'peer' abusive supervision)). Hannah et al. (2013) observed an interaction between subordinates' own reports of abuse and the average level of work unit member abuse in predicting subordinates' ethical behaviors and intentions among soldiers deployed in combat. Subordinate's own experience of abusive supervision was more strongly related to outcomes when coworker unit abusive supervision was lower. This study drew from a self-regulation perspective of abusive supervision, emphasizing the strength of moral standards and moral courage as mediators of these interactive effects. Drawing from a social exchange perspective, Peng et al. (forthcoming) examined the interaction of peer and own abusive supervision on employees' leader–member exchange perceptions and

affect-based trust in peers. These exchange variables partially mediated the interactive effects of own and peer abusive supervision on task performance and helping behaviors directed toward peers. Only employees who were low in both own and peer abusive supervision exhibited high levels of helping behavior and task performance, a pattern consistent with Hannah et al. (2013).

In sum, a higher level of work unit abuse is associated with weaker relationships between individual abusive supervision and subordinate outcomes, reflecting a pattern of substitution moderation. Thus, the social context of abusive supervision affects how employees respond to their own abusive treatment by the supervisor. Employees are especially impacted by such abusive behavior when they are singled out for abuse. It is also noteworthy that the findings of the studies reviewed above concerning own and coworkers' experiences of abusive supervision are not consistent with the deontic justice literature, in which coworkers' experiences of injustice are met with aversive psychological reactions and aggressive responses, much as the individuals react to experiencing the injustice themselves. Peng et al. (forthcoming) noted that conflicting results across the two approaches may be due to the fact that research on deontic reactions to injustice has been conducted primarily in laboratory settings. Unlike a workplace, laboratory participants would be less likely to fear repercussions for confronting or reporting an abusive supervisor or expressing moral outrage for the abuse.

Cross-Cultural Research

Abusive supervision research using samples from outside of the United States has been growing steadily, spanning many different regions of the world (e.g., Australia, Belgium, Canada, China, India, Philippines, Singapore, Slovenia, South Korea, New Zealand, Nigeria, Norway, and Taiwan). Hu et al. (2011) compared participant responses from Taiwan and the United States and found that employees generally experienced abusive supervision as a single latent construct. However, Taiwanese employees reported that supervisor belittling was more essential to their conceptualization of 'abusive supervision' than workers from United States. Belittling behaviors may reflect an underlying construct of 'saving face,' which Confucianism-based societies (e.g., Taiwan) value as an important part of interpersonal interactions (House et al., 2004).

Power distance orientation has been the most commonly studied cultural construct in the abusive supervision literature. It is defined as the extent to which individuals accept an unequal distribution of power in organizations and institutions. As one might expect, subordinates who score high on power distance orientation exhibit weaker relationships between abusive supervision and subordinates' psychological health and job satisfaction (Lin et al., 2013). Subordinates high in power distance orientation viewed abusive supervision as more fair and were less likely to react with interpersonal deviance than subordinates low in power distance orientation (Lian et al., 2012a). Another cultural predisposition variable of interest to abusive supervision scholars is Chinese traditionality (i.e., the degree to which an individual is fatalistic and values respect for authorities and elders). Liu et al. (2010) observed that the relationship between abusive supervision and supervisor-directed deviance was stronger for individuals who did not report high traditionality.

Preventing and Managing Abusive Supervision

Preventing or managing abusive supervision ought to be on the forefront of research given its deleterious impact on employees and organizations. Yet there have been few published empirical assessments of abusive supervision intervention programs. A study conducted by Leiter et al. (2011) is an exception. They evaluated the efficacy of a general civility intervention in a sample of health care workers. The program consisted of trained facilitators meeting with employees on a weekly basis for 6 months. Training content included learning to identify incivility behaviors (e.g., rude and condescending behavior), effectively respond to incivility, and practicing new ways to interacting positively. Compared to a contrast group that did not formally participate in the sessions, treatment group participants reported lower experienced incivility from supervisor and coworkers, lower report of self-enacted incivility behaviors, and higher civility within the work unit overall (e.g., spirit of teamwork in work group, disputes are resolved fairly).

A number of legislative developments may encourage organizations to devote greater attention to preventing abusive supervision. In many countries, employees may seek redress in civil courts for abusive supervision as well as for coworker abuse. As of 6 February 2014, 26 state legislatures in the United States had introduced the Healthy Workplace Bill, which includes specific penalties for abuse of employees. Similar legal protections have been become law in other countries, including Australia, Belgium, Canada, Denmark, Finland, France, Great Britain, Iceland, Ireland, and Norway.

Conclusion

Given the detrimental impact of abusive supervision on employee outcomes, researchers have examined a wide range of antecedents and mechanisms through which abusive supervision arises and affects victims' behaviors, attitudes, and well-being. The literature has become very vibrant in more recent years, broadening in the depth and scope of research questions examined, improving in methodological sophistication, and engaging a fairly large network of scholars worldwide. While the future of abusive supervision research looks promising, we hope that abusive supervision scholars and those investigating similar constructs (e.g., supervisor incivility) can begin to work together in addressing their common questions. We also encourage researchers to become more active in producing evidence-based approaches for preventing supervisory abuse and for enabling workers to more effectively confront abuse without suffering adverse personal consequences.

Abstract

Supply chain management is a critical aspect of conducting any business. In this article, we provide an overview of the advancements in supply chain management. In the initial section, we present alternative definitions and key issues related to supply chain management followed by a discussion of complexities associated with managing supply chains. Subsequently, we discuss major inefficiencies of poor supply chain management. Finally, a brief summary of research activity to date and a discussion of future challenges related to supply chain management are presented.

Introduction

Supply chain management is one of the most essential aspects of conducting business. Many people outside of the direct community (in research and industry) do not realize this because an ordinary consumer often experiences only its effects. Recall the times when the item that you wanted was not available in your favorite garments or grocery store, recall how many times you got a great 'deal' at the end of the season, recall the sudden increases in gas prices due to shortages, recall the times when your e-commerce site promised availability but later could not send the required product or sent you the wrong product, or recall the times when your customized product (like a personal computer or kitchen cabinet) was delayed to a great extent. All the above and several other experiences that consumers have on a routine basis are direct consequences of supply chain practices followed by firms. As opposed to business-to-consumer transactions, supply chain practices have immediate impact on business-to-business transactions.

In the late 2000s, due to glitches of its extensively outsourced supply chain for Dreamliner 787, Boeing experienced substantial delay in launching the new aircraft and incurred more than $2 billion in charges to support and expedite component supplies. Less than 2 years after the first delivery of Dreamliner 787 in 2011, Boeing was ordered to shut down production of the aircraft due to quality issues with batteries. In 2007, Mattel had to recall tens of millions of toys made in China, which becomes poster child for concerns about quality of offshore goods. While some firms suffered from consequences of bad supply chain management, firms such as Amazon, Wal-Mart, and Zara have consistently outperformed competition due to great supply chain capabilities.

Definition

Since Keith Oliver, a consultant at Booz Allen Hamilton, coined the term in 1982, supply chain management has evolved from originally being understood as only logistics to a complex multifunctional corporate undertaking that ranges from procurement and demand forecasting to distribution and after-sales service. Supply chain management is such a vast topic that as a result people often give it a different definition based on their own personal experience. To some, supply chain management is all about managing the supplier base, determining what to outsource and to whom, and managing relationships with the various suppliers. To some others it is efficient ways of transferring goods from one place to another taking into account the distribution and transportation costs. To another set of people it is all about how the different firms in the distribution channel or value chain are integrated in terms of information systems and inventory management practices. To yet another group it is effective management of fixed and variable assets required for running the business. In a sense all these definitions are like the blind men defining the elephant based on its different organs. A comprehensive definition of supply chain management can be given as follows.

A supply chain is the set of entities that are involved in the design of new products and services, procuring raw materials, transforming them into semifinished and finished products, and delivering them to the end customers (Swaminathan, 2001). Supply chain management is efficient management of the end-to-end process starting from the design of the product or service to the time when it has been sold, consumed, and finally disposed of by the consumer. This complete process includes product design, procurement, planning and forecasting, production, distribution, fulfillment, and after-sales support (see **Figure 1**).

Supply chain management issues can be classified into two broad categories – configuration and coordination. Configuration-level issues relate to the high-level design and basic infrastructure of the supply chain and coordination-level issues relate to the tactical decisions and day-to-day operations of the supply chain.

Configuration-Level Issues

Supply Base Decisions

How many and what kinds of suppliers to have? Which parts to outsource and which to keep in-house? How to standardize and streamline procurement practices? Should one use vertical marketplaces for auctions or should one invest in developing highly integrated supply partnerships? How long or short contracts with suppliers should be?

Figure 1 Supply chain process.

Plant Location Decisions

Where and how many manufacturing, distribution, or retail outlets to have in a global production distribution network? How much capacity should be installed at each of these sites? What part of the supply chain should be kept onshore, near-shore, or offshore? What kind of distribution channel should a firm utilize – traditional brick and mortar, direct to consumer via Internet or phone, or a combination?

Product Portfolio Decisions

What kinds of products and services are going to be supported through the supply chain? How much variety to provide to customers? What degree of commonality to have across the product portfolio?

Information Support Decisions

Should enterprise resource planning software be standardized across functional units of a firm? Should the supply chain work on standard protocols such as extended markup language (XML) or on proprietary standards?

Coordination-Level Issues

Material Flow Decisions

How much inventory of different types of products should be stored? Should inventory be carried in finished form or semi-finished form? How often should inventory be replenished? Should a firm make all of its inventory decisions or is it better to have the vendor manage the inventory? Should suppliers be required to deliver goods just in time?

Information Flow Decisions

In what form is information shared between different entities in the supply chain – paper, voice via telephone, electronic data interchange (EDI), XML? To what degree does collaborative forecasting take place in the supply chain? What kind of visibility is provided to other entities in the supply chain during execution? How much collaboration takes place during new product or service development among the supply chain partners?

Cash Flow Decisions

When do suppliers get paid for their deliveries? What kinds of cost reduction efforts are taken across the supply chain (or expected of suppliers)? In a global firm, in which currency will a supplier be paid?

Capacity Decisions

How to optimally utilize the existing capacity in terms of manpower and machines? How to schedule on a manufacturing line to complete jobs on time? How much buffer capacity to have for abnormal situations with excess demand?

As is evident, configuration and coordination issues are interdependent. Configuration issues can be viewed as strategic long-term decisions whereas coordination issues are medium- to short-term decisions. Generally, firms develop a strategy for the configuration-level decisions and then constrain the coordination decisions based on those.

Complexities Associated with Supply Chains

As evident from discussions in the earlier section, supply chain management spans several functional and geographical areas. This introduces complexities both in terms of design and execution of supply chains. Some of the pertinent factors that complicate supply chain management decisions are as follows.

Multiple Agents

Supply chain issues need to be decided by different entities sometimes having different interests. For example, a retailer may want that the distributor provide very high availability for the products but at the same time not charge anything additional to the retailer. The distributor may sometimes agree to that but in turn may want information about actual customer sales which the retailer may not want to share. Even when decisions have to be made within the same firm there could be incentive issues. For example, the marketing or sales department, typically a revenue center, presents the future demand forecast to the manufacturing department that is a cost center. Clearly, there is incentive for the former to overforecast and the latter to underproduce (as compared to the forecast). This creates several difficulties while deciding on the amount of inventory to be stocked. Another related issue is encountered where the marketing department may push for huge amount of

variety in the product/service offerings; the manufacturing department may not want to embrace that because additional complexities are created during execution.

Uncertainty

Accurately matching supply and demand is the ultimate goal of effective supply chain management but that is complicated by uncertainty at various levels of the process. There is uncertainty in product and technology development, in predicting customer demand, in day-to-day operations and manufacturing, and supply. Typically, uncertainty creates more inefficiency in the system. For example, if the final demand for a sweater at a store cannot be predicted accurately then the firm either stocks too little (in which case it suffers from stock-outs) or produces too much (in which case it has to salvage the inventory through a huge sale at the end of the season). Similarly, the uncertainty in supply may necessitate additional buffer inventory.

Information Asymmetry

Since supply chain processes extend across multiple functional units within a firm and often across different firms there is a high degree of asymmetry in terms of information. This is caused primarily by two main reasons – one relates to lack of adoption of information technology and the other relates to reluctance to share information with other supply chain partners. The lack of information causes several problems during actual fulfillment. For example, when a consumer goes to an e-commerce site and buys an item off the electronic catalog, the consumer expects to receive the product on time. The consumer is not aware that the inventory status on the product may be updated only once a week and that the information on the site may be outdated. As a result, the consumer is disappointed when the product does not arrive on time.

Lead Time

Each and every task in the supply chain process needs time to be completed and the resources (labor, machines, or computers) have limited processing capacity. As a result, not all tasks can be completed after the actual demand is known and some of the tasks need to be done up front (which may or may not get utilized based on the actual demand realized). Further, the limited capacity associated with the resources creates variability in the actual realized lead-time, which in turn necessitates greater resource requirements at the next stage in the supply chain. The above complexities lead to several types of inefficiencies in the supply chain that are often perceived as the 'bad effects' of inefficient supply chain management. Some of the major inefficiencies can be classified into the following categories.

Competition

When making supply chain decisions, firms have to take market competition into consideration. For example, forming exclusive trade relationship with key suppliers helps prevent proprietary technology to be leaked to competitors who may source from the same suppliers. As another example, firms' outsourcing decisions can be shaped by what competitors do (see Feng and Lu, 2012). In the computer and electronics industries, many companies rely on contract manufacturers to assemble final products. Due to their location in low-cost regions and scale economies, these contract manufacturers generally have a lower cost structure than original equipment manufacturers. For a long time, Dell, operated its own assembly plants in North America to support its build-to-order model. Under increasing market pressure to lower costs, Dell had to change its supply chain strategy by outsourcing assembly work to contract manufacturers, a strategy that has long been adopted by its key competitors.

Inefficiencies of Supply Chain Management

Poor Utilization of Inventory Assets

One common effect of poor supply chain management is having excess inventory at various stages in the supply chain, at the same time having shortages at other parts of the supply chain. Since inventory forms a substantial part of working assets of a firm, poor management could lead to huge inefficiencies. Lee and Billington (1992) provide an excellent overview of pitfalls and opportunities associated with inventory management in supply chains.

Distortion of Information

Another effect relates to lack of visibility of demand and supply information across the supply chain which causes the bullwhip effect. This effect describes how a small blip in customer demands may get amplified down the supply chain because the different entities in the supply chain generate and revise their individual forecasts and do not collaborate and share actual demand information. Lee et al. (1997) describe the causes and controls for this effect.

Stock-Outs

Poor supply chain management also results in late deliveries and large stock-outs. Fundamentally, these effects are caused due to an inability of the firm to predict the requirement for raw material and equipment capacity together with the uncertainty associated with obtaining deliveries of products on time from its suppliers. Fisher et al. (1994) describe how accurate forecasts in the apparel industry could potentially reduce this inefficiency.

Customization Challenges

As the degree of customization has increased in the marketplace, one of the immediate effects of poor supply chain management relates to late deliveries of customized products. Firms are developing several strategies in order to provide variety while keeping costs under control. These include delaying differentiation of the product and introducing more commonality and modularity in product lines (see Swaminathan and Tayur, 1998).

New Developments in Supply Chain Management

Global Supply Chains

In the increasingly globalized world economy, even a small manufacturing firm may face the challenge of managing an oversea supply relationship. Globalization is not a new phenomenon, but the globalization trend developed in the first decade of the twenty-first century created a more flattened world than history has seen. However, in the recent years the cost differential between the emerging economies and the developed ones is gradually disappearing. This forces many firms to reconsider their supply chain configurations, particularly their cost-driven offshoring strategy. In the last few years, some manufacturing firms, large and small, have brought offshored production back onshore. Meanwhile, the growing market size of the economies outside the developed countries has made expansion of one's global supply chain footprint a more attractive option. Striking the right balance between onshore and offshore sourcing will continue to be a key task in firms' supply chain strategy.

Sustainable Supply Chains

In the last decade, building sustainable supply chains has gathered tremendous attention from environmentalists, NGOs, and businesses. This society wide sustainability initiative has influenced many firms' supply chain strategies. For instance, Wal-Mart in 2005 launched three overarching sustainability goals: (1) use 100% renewable energy; (2) produce zero waste; (3) sell products that sustain our resources and environment (Denend and Plambeck, 2007). To achieve these goals, the company examined various aspects of its supply chains to identify areas that offered the most potential for sustainability. And it used various incentives to motivate its suppliers to contribute to its sustainability goals.

Humanitarian Supply Chains

Between 1974 and 2003, there were 6637 natural disasters worldwide with more than 5.1 billion people affected and a reported damage of $1.38 trillion USD (Ergun et al., 2009). Although the occurrence of these events was hard to forecast, the social and financial impact could have been reduced with proper planning. In particular, humanitarian supply chains, i.e., supply chains for disaster planning and response, can be well designed and maintained for the purpose of quick response and relief effort after disasters strike. Humanitarian supply chains differ from regular supply chains in terms of their supply and demand patterns. Refer to Ergun et al. (2009) for a detailed review on the subject. Another important type of humanitarian supply chains relates to delivery of essentials (food supplements, bed nets, and vaccines) to people in need during nonemergency times (see Swaminathan, 2009; Komrska et al., 2013).

New Technologies Impacting Supply Chains and Big Data

In the last two decades, digital technologies have had a lasting impact on how supply chain activities are conducted. According to a recent study by Intermec, a leading supply chain solutions provider, the top 10 technologies that have the most impact on supply chain operations include: (1) comprehensive connectivity – from 802.11 wireless LAN technologies, cellular networks, and Bluetooth; (2) voice and GPS communication integrated into rugged computers; (3) speech recognition; (4) digital imaging; (5) portable printing; (6) 2D and other bar coding advances; (7) radio-frequency identification; (8) real-time locating system; (9) remote management; (10) wireless and device security.

The proliferation of the aforementioned digital and communication technologies in business and consumer uses has created tremendous amount of data on business transactions, logistical activities, customer characteristics, etc. According to IDC, approximately 750 exabytes (EB) of data were created online in 2009, and it is forecasted to exceed 35 zettabytes (ZB) by 2021. Big data, according to Gartner, is defined as "high-volume, high-velocity, and/or high-variety information assets that require new forms of processing to enable enhanced decision making, insight discovery and process optimization." The real impact of big data on improving supply chain efficiency is yet to be seen, and companies are only starting to tap into the potential offered by the vast amount of data being collected in their information systems. In the face of explosive growth of data, the information industry is going through a revolution, and sophisticated tools are yet to be developed to analyze supply chain-related data for performance improvement.

Supply Chain Research: Past, Present, and Future

The science related to supply chain management traces its history back to the early 1950s when several researchers were interested in understanding the optimal policies related to inventory management. One of the first pieces of work in this stream relates to the models developed by Clark and Scarf (1958) for managing inventories at multiple echelons. Several hundreds of researchers have studied related inventory problems under stochastic and deterministic environments since the 1950s.

This research is captured concisely in the research handbook edited by Graves et al. (1993). There is a large amount of literature in the area of transportation and distribution as well as plant location models in the context of supply chain management. Traditional researchers focused on developing optimal policies and rules for specific supply chain issues assuming a centralized control of the supply chain. In the 1990s researchers have started to study problems which take a decentralized multiagent approach to analyzing supply chain problems, integrate information availability across the supply chain with logistics decisions, develop new models for supply contracts, and demand forecasting and integrate product design with supply chain management. A collection of prominent pieces of research in this area is contained in Tayur et al. (1998) and de Kok and Graves (2003). After several decades of studying supply chains with mathematical models, researchers started to use data and empirical methods to validate supply chain theories and to systematically characterize supply chain practices. For example, using industry-level U.S. data, Cachon et al. (2007)

document the strength of the bullwhip effect, i.e., the phenomenon that demand variability increases moving from the downstream of a supply chain to the upstream. Using firm-level data, Cachon and Olivares (2010) examine the factors that contribute to the difference in finished goods inventory between several leading auto manufacturers. The empirical stream of research will continue to grow as researchers become more creative in finding relevant data on supply chains.

In addition to academic research, several firms in the 1990s developed successfully and employed large analytical and simulation models for supply chain optimization and execution. Arntzen et al. (1995) describe one such system developed for Digital Equipment, and in 2004, Motorola was awarded the Franz Edelman Award by the Institute for Operations Research and Management Sciences (INFORMS) for using operations research methods to launch a comprehensive online negotiation system to support the company's sourcing process which led to $600 million in savings.

In the twenty-first century, firms face severe challenges in terms of global competition and customer requirement for greater variety, shorter and reliable delivery times, and lower prices. The advent of e-commerce has created immense opportunities but at the same time has made firms more vulnerable to logistics pitfalls. Today customers do not just buy products but they buy delivered products. As a result fulfillment is as important as making the sale. As opposed to traditional channels where inventory could be stored to hide other inefficiencies in terms of lead-time and poor forecasts, in the fast-paced electronic business environment such arrangements are not as useful. As a result, firms are beginning to pay more attention toward supply chain management. Both business-to-consumer and business-to-business e-commerce environments have introduced several issues related to supply chain management which are likely to be studied by researchers in the near future.

The prevalence of the Internet has led to the development of vertical marketplaces that promise to reduce the inefficiencies in the buying process in several industries. On one hand, these marketplaces are likely to reduce the cost of goods for the manufacturer due to more competition leading to better prices. This line of thought indicates that in the future supply chains may be more agile and supplier relationships may be short-term oriented. On the other hand, several firms realize that greater benefits can be attained if some of these marketplaces can in fact be used for process integration and collaboration across the supply chain. In such an environment, firms need to develop greater trust so that they would be willing to share information with their supply chain partners. Researchers today are trying to identify under what conditions one or the other scenario may play out and what kinds of new models and analysis need to be developed. A related effect of the Internet is the expansion of global supply chains. Today it is much easier for any supplier located in a remote part of the world to bid on contracts from large firms in developed nations with whom they may not have done business in the past. Issues related to coordination of global supply chain management are likely to be an integral part of supply chain management research in the future. Another important research topic is sustainable supply chain management. Traditionally, researchers have only concerned themselves with efficient movement of goods from supplier to the customer. Now a greater number of researchers are studying problems related to disposal of used products, refurbishing old products, making packaging more environmentally friendly, and basing supplier selection on environmental criteria in addition to traditional criteria related to cost, quality, and reliability. Another new stream of research is the study of supply chains in the service industry. As opposed to traditional manufacturing-oriented supply chains, service supply chains are more complicated due to the inability to store inventory. Uncertainty is handled in those cases using additional buffer capacity. Finally, researchers are beginning to look at behavioral issues such as trust, bounded rationality, mental accounting, etc. that may arise in supply chain management.

Suprasegmentals

Carlos Gussenhoven, Radboud University Nijmegen, Nijmegen, The Netherlands

Abstract

The prosodic structure of languages is divided into word prosody and sentence prosody. Beyond an organization of vowels and consonants into syllables, languages may have segmental length, tone, and stress, in any combination. The prosodic structure of words can be inferred from their pronunciation by abstracting away from the phonological phrasing structure (the prosodic hierarchy) and the tonal structure of the intonational melody. Boundary tones delimit larger phonological phrase types and some languages have phrase-internal tones (pitch accents). Word prosody distinctions encode lexical and grammatical morphemes, prosodic phrasing imperfectly reflects syntactic structure, and melodic contrasts signal discourse and focus meanings.

Introduction

The prosody of language covers all aspects of speech that are not related directly to the articulation of the vowels and consonants in linguistic expressions, a negative definition that is echoed by the traditional term 'suprasegmentals.' The topic can be approached in positive terms either from the perspective of the phonetic signal or from that of the linguistic structure. The first perspective leads to the analysis of the acoustic signal into four dimensions of variation. These are the spectrum, duration, intensity, and fundamental frequency. It was pointed out by Ilse Lehiste (1970) that the last three dimensions can be observed as properties of the first. We can say how long and how intense the speech signal for some vowel is and what its fundamental frequency is, but we cannot say how intense duration is or how long the fundamental frequency, she argued. In this sense, suprasegmental features are overlaid features, while spectral features are inherent. The second perspective presupposes an understanding of the prosodic structures of languages. It seems fair to say that this understanding has not yet achieved the level of analytic accuracy that has been reached for segmental structures, but considerable progress has been made in the past decades.

Two general points are made before we move on to linguistic structures. One is that the neat distinction between spectral variation and the three suprasegmental dimensions of variation must blur again, because phonological elements are famously promiscuous with respect to the four dimensions of phonetic variation. Thus, linguistic categories that typically are encoded in one of the suprasegmental dimensions of variation frequently also make use of spectral variation, including variation in voice quality. This applies to stress and tone as well as to intonation. The second point is that a great deal of the communicative impact of intonated speech is to be attributed to paralinguistics, the systematic variation that speakers of all languages use to signal universal meanings not encoded in the linguistic structure (Ladd, 2008). Variations in overall pitch range, for example, may signal such general meanings as surprise, authoritativeness, and emphasis (Ohala, 1994). Generally, paralinguistic meanings can be seen as metaphorical interpretations of anatomical and physiological effects on vocal fold vibration (Gussenhoven, 2004, Chapter 4). Ohala's Frequency Code connects the effect of larynx size on frequency of vocal fold vibration with the inferred size of the animal or human producing it, causing high pitch to signal 'small' meanings like submissiveness, vulnerability, and uncertainty and low pitch to signal their opposites. The disentanglement of these paralinguistic meanings – from the meanings encoded in intonational morphemes – will remain an intriguing area of research. A related point is that intonation differs from other components of linguistic structure in that deviations in the timing or pitch range from a canonical pronunciation will trigger paralinguistic interpretations of speaker intentions, while comparable spectral deviations may be interpreted just as indications of articulatory casualness or of temporary physical constraints on speech production.

The approach adopted in the remainder of this article takes the phonological representation as the starting point, selecting those elements in that representation whose realization typically or in large measure involves nonspectral variation, much as has been done in Fox (2000). Since few languages will exemplify all the prosodic phenomena that have been reported, this approach inevitably looks at the languages of the world as a single body of data and will identify aspects of prosodic structure cross-linguistically. One way to divide the topic is to separate word prosody from sentence prosody.

Word Prosody

Broadly, the phonological structure of words can be more than a syllabified string of consonants and vowels in three ways. One is the existence of long segments by the side of short ones, a second is the presence of metrical structure, and a third is the presence of lexical tone. Languages do not require any of these properties. French, for instance, has been claimed to be a language without any word prosodic structure, which is supported by the finding that French listeners perform poorly in short-term memory tasks involving the position of the stress (Peperkamp and Dupoux, 2002).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.52024-8

Quantity

When duration differences are encoded in the phonology, they are referred to as quantity differences or length differences. Vowels as well as consonants may contrast for quantity. Finnish has quantity contrasts for both consonants and vowels, as has Japanese. Hawaiian contrasts long and short vowels only, while Italian contrasts long and short consonants only. Spanish and French have neither long vowels nor geminate consonants. Quantity is described with the help of moras, which make up the syllable rime, the part of the syllable minus the initial (onset) consonant(s), but including the closing (coda) consonants. A Finnish syllable rime containing a short vowel, like the first syllable of *eri* 'different,' has one mora, while a syllable with a long vowel, like the first syllable of *vaara* 'danger,' has two. A long vowel is prosodically identical to a short vowel plus a coda consonant, making *vaara* and *arki* 'workday' prosodically equivalent. Three moras occur in the first syllable of *arkki* 'sheet of paper' or *aarre* 'treasure,' where the first half of the geminate consonants [kk] and [rr] is a coda in the first syllable and the second half an onset in the second. Syllables with four moras, like [aark] in the proper name *Jotaarkka*, are extremely rare (Suomi et al., 2008). Japanese syllables have one, two, and very rarely three moras, as illustrated by, respectively, [o] 'tail,' [on] 'speech sound,' and [aan] in (*Nyuu*) *Jiraando* '(New) Zealand.' Trimoraic rimes in which all three moras are filled by the same segment are extremely rare and have been reported for Estonian and related languages and for Dinka. The most frequent phonological context of geminates is intervocalic. A language with word-initial, word-medial, and word-final geminates has been reported in Kraehenmann (2001), together with a discussion of their moraic representation.

Word Prosodic Metrical Structure

A language has metrical word structure if the syllables in a word differ in prominence or weight from other syllables in the same word. In such cases, the more prominent syllable is stressed and the less prominent ones are unstressed. Stress systems show a number of tendencies. One of these is alternation, the tendency for stressed and unstressed syllables to alternate. Another is culminativity, the restriction to a single most prominent syllable. When there are two or more stressed syllable, the most prominent one is referred to as the primary stress (aka main stress, word stress) and the other or others as secondary stress. A third tendency is for the main stress to occur at or near a word edge, the demarcative tendency. These three aspects are illustrated by Pintupi (Australia), where words always have the primary stress on the first syllable, while in careful pronunciation, secondary stresses occur on odd syllables after the first, as in the 12-syllable [ˈjumaˌɻiŋkunˌtamaˌɻacaˌnampaˌluɻa] 'avoid (the camp) of all those mothers-in-law' (stresses inferred, Hansen and Hansen, 1969). To capture this alternation, stress systems are described in terms of feet, disyllabic strong-weak (trochee) or weak-strong (iamb) templates, which are assigned sequentially through the word. Pintupi is analyzed as having trochees assigned from left to right, which accounts for the fact that any odd numbered word-final syllable is not stressed (i.e., the last two syllables of words with an odd number of syllables are unstressed). Culminativity and demarcativeness are described by a higher level prominence assignment to either the left or right. Further complexity may be due to interdependencies between stress and the segmental composition of the syllable. In quantity-sensitive languages, long vowels, or long vowels and closed syllables, do not tolerate being in a weak position, and thus will interrupt any regular count through the word. Hawaiian is a quantity-sensitive trochaic language that assigns feet right-to-left, so that [ko'hola] 'reef' has penultimate stress, but [koho'laa] 'whale' has final stress (Elbert and Pukui, 1979). Another type puts no limit on the distance of the heavy syllable from the word edge (unbounded feet). Classical Arabic has initial stress, as in ['balaħatun] 'date,' but if there is a later heavy syllable, the rightmost one has the stress, as in [manaa'diilu] 'kerchiefs.'

At the right edge, the most frequent location of main stress is penultimate (e.g., Mohawk, Polish, Quechua, Swahili), but final and antepenultimate locations are common, often in the same language. On the left, the most frequent position is initial (e.g., Bengali, Czech, Finnish, Icelandic), but stress on the second syllable is common. Extrametricality is a descriptive device used to explain regular or exceptional stress locations further away from the edge. Exceptional antepenultimate stress in languages with regular penultimate stress can be explained by making the last syllable or the last consonant 'invisible' to foot assignment. The opposite ploy is called catalexis, the postulation of an extra syllable at the word end, which is presumed to be parsed as a weak syllable in a foot. Languages may have lexicalized stress within an otherwise-regular stress system, in which case stress will be lexically contrastive, as in English '*insight* vs *in'cite*. Stress location may be sensitive to morphological structure, as in Spanish '*ablo* vs *a'blo* or English '*overhaul* (noun) vs *over'haul* (verb). It generally is believed that no language *only* has lexicalized stress, such that stress locations do not yield to any generalization. A recent survey is van der Hulst et al. (2010).

From a distributional point of view, the notion stress is reasonably uncontroversial. Hyman (2006) characterized a language as having 'stress' if it occurs on a syllable, as opposed to a mora; if it is culminative, it being the most prominent syllable in the word; and if it is obligatory, meaning that there should be no words without stress, discounting unstressed words that cannot appear in an utterance without stressed words, like the English articles. From the perspective of its phonological and phonetic substance, stress is more elusive. On the assumption that the origin of stress is a rhythmic alternation of hyper- and hypoarticulation, it is not surprising that stressed syllables are typically longer and pronounced with greater articulatory care than unstressed syllables, resulting in more canonical articulations with less articulatory reduction and a sustained amplitude across the spectrum (e.g., Sluijter et al., 1997), which enhances intelligibility (Lu and Cooke, 2009).

In many languages, hyperarticulation tendencies are reflected in the phonology. English is a good example of a language in which the composition of a stressed syllable is phonologically different from an unstressed one. Unstressed syllables usually have a three-way vocalic distinction, with details depending on the dialect (Bolinger, 1986: p. 347 ff), as

illustrated by the vowels in the second syllables of *cranial*, *usual*, and *mineral*. Any other vowel would attract the stress, as in *denial*, *bestowal*, *betrayal*, and so on. Second, the stressed syllable in English acts as the attractor of the intonational pitch accent. Less than 40% of the syllables in English prose texts are stressed, and in a competent reading, only about 65% of these are pitch accented. Stressed syllables of other languages may have similar phonological features distinguishing them from unstressed syllables. In Egyptian Arabic, stressed syllables are always pitch accented, for instance (Hellmuth, 2007). In Finnish, which has a quantity distinction on both consonants and vowels and primary stress on the first syllable, all vowels that appear in stressed syllables also can appear in unstressed syllables. (According to Suomi et al. (2008: p. 77), some of the more complex syllable structures occur only in initial position.) If languages have no segmental distinction between stressed and unstressed syllables, the stressed syllable may be variably pitch accented (Beckman and Edwards, 1994), or else the difference is phonetic. Spanish distinguishes unaccented stressed and unstressed syllables with the help of a phonetic duration difference (Ortega-Llebaria and Prieto, 2010).

A fairly widely honored, but deeply confusing, tradition in English phonology is to collapse unaccented stressed and pitch-accented stressed syllables into a single paradigm of syllables with different degrees of stress. The presence of a pitch accent on a word's stressed syllable does not alter any of its segmental features, but it adds pitch features in and around the accented syllable that make up the intonation contour of the utterance (Bolinger, 1986). The determination of what is a stressed syllable belongs virtually exclusively in the lexicon; a minor role for syntax is found in the obligatory stressed pronunciation of function words before deletion sites, as illustrated in *Sue can* (kən) *come, but I don't know if Gary can* (kæn) (Kaisse, 1985; Selkirk, 1986, 1995). The reasons for the presence of pitch accents on words are more varied. They are morphological, phonological, or syntactic or they have to do with information structure (cf Gussenhoven, 2011). Compound formation may be marked by lack of a pitch accent in the second constituent, as in *COURSE requirements*, while phonological phrasing is responsible for the difference in accentuation in *The gave [the CHInese DISHES]φ* ('They gave the dishes that were of Chinese origin') *They gave [the CHINESE]φ [DISHes]φ* ('They gave dishes to the Chinese') (Hayes, 1989). Syntax is involved in the generalization that predicates may lack a pitch accent when adjacent to an argument. The predicate–object combination in *I used chopsticks* typically is pronounced with a pitch accent on *CHOPsticks* only, while the noun phrase *USED CHOPsticks* will have two pitch accents (Schmerling, 1976; Selkirk, 1986; Birch and Clifton, 1995). A condition on the deletion of the accent on the verb is that the proposition should be eventive (Gussenhoven, 1983; cf the distinction between stage-level and individual-level predicates in Kratzer, 1995). For instance, the verb in *Too many cooks spoil the broth* has an obligatory pitch accent (in addition to the pitch accents on *Too*, *cooks*, and *broth*), because the sentence is a 'contingency' sentence ('If there are …' etc.). The absence of that pitch accent would invite the interpretation that the number of cooks that spoil the broth is in fact large. Information structure is involved in the difference between *Is that an ENTrance requirement or a COURSE requirement?* In the literature that collapses the presence of a pitch accent with word-stressed syllables, the compound *COURSE requirements* would be said to have secondary stress on the penultimate syllable of *requirements* and primary stress on *course*, while in the case of the contrastive focus on *course* in *COURSE requirement*, the word *requirement* would be said to be deaccented. The prosodic structures of these two expressions are the same, however.

Lexical Tone

A frequently applied morphosyntactic criterion for lexical tone, and hence of the notion *tone language*, is whether tone(s) enter into the specification of words or morphemes. If they do, the language is a *tone language*. Examples are found in Asia (Sino-Tibetan languages, Japanese), Africa (Bantu languages, Khoi-San languages, Nilo-Saharan languages), and many languages in the Americas (Yip, 2002). Mandarin (Sino-Tibetan) has five words that consist of the syllable [ma]. Four of these have a lexical tone: [ma˥] 'mother,' [ma˧˥] 'hemp,' [ma˨˩˦] 'horse,' [ma˥˩] 'scold,' where the Chao tone letters give an iconic indication of the pitch contour to the left of a vertical bar, which indicates the pitch span (Chao, 1930). One [ma] is toneless, a question particle ('neutral tone'). Notation of tones in tone languages spoken in Africa and, to a lesser extent, in the Americas use accents over vowels (high level [á], low level [à], mid level [ā] falling [â], rising [ǎ], etc.), whereby long vowels are given as [aa], as in Mamvu [máàkà] 'type of seasoning' vs [màákà] 'cat.' Frequently, tone is involved in the morphology, as in Makonde [nìndì tálèékà] 'I cooked' vs [nìndà tàlèékà] 'I will cook' and Mamvu [áfù] 'man,' [àfú] 'men' (examples from Kaji, 1999). Estimates of the proportion of tone languages run from 50% (Maddieson, 1978) to 70% (Yip, 2002).

A subclass of tone languages frequently is singled out as being pitch-accent languages. Hyman (2009) argued that languages that have been identified as such differ from other tone languages in the distribution of the tone contrast over the word. Tone contrasts typically are not located on every syllable or mora of the word. Sino-Tibetan languages may have very 'dense' distributions, with only a minority of words, like the interrogative particle [ma] of Mandarin, having no tone of their own ('neutral tone'). Japanese is an example of a language with a 'sparse' distribution of tone. Only about half of the Japanese words, the accented words, have a lexical pitch accent (HL), the other half being lexically toneless, or unaccented. Since the pitch accent can be lexically specified once per word for any syllable, the number of prosodic patterns for words of n syllables is $n - 1$. A triplet of disyllables is [ha˥si] 'chopsticks,' [hasi˥] 'bridge,' and [hasi] 'end,' where the right hook indicates a pitch accent on the preceding syllable.

The study of tonal structures in African languages in the second half of the last century led to the development of autosegmental representations (Goldsmith, 1976), whereby the phonological specification of words consists of at least two parallel linear tiers, in which the elements (the 'segments') are synchronized by means of associations. In

the case of the synchronization of tones on the one hand and vowels and consonants on the other, the associations are not direct, but rather they are mediated by the prosodic structure. Some language use the syllable as the tone-bearing unit (TBU), others the mora, whereby the tone-bearing status of the mora is usually conditional on the presence of a vowel or sonorant consonant in it, thus excluding obstruent consonants from being tone bearers. Although the Japanese pitch accent is assigned to a syllable, the tones associate with moras. That is, even though the number of moras in [hai] is the same as that in [hasi], there could be only two words with the monosyllabic structure, [hai] and [hai˥], both of which happen to exist, 'lungs' and 'yes,' respectively. The associations of the lexical pitch accents with the previous five words are shown in (1) for the disyllables and (2) for the monosyllables. Structurally, there is no (2b).

```
(1) a.   h a s i        b.   h a s i          c. h a s i
         |   |                  |
         H   L                 H L
         'chopsticks'           'bridge'       'edge'

(2) a.   h a i          b.   -                 c.  h a i
         | |
         H L
         'yes'                                 'lungs'
```

Autosegmental representations explain, as in (1a) and (2a), how the same tone string, here HL, can have different syllabic pitch effects. The first syllable in (1a) is high, the second is low, and the syllable in (2a) has a fall. For this reason, linguists are careful to distinguish phonological tones from their phonetic realization.

Tone languages spoken in Africa have varying degrees of density. Somali is comparable to Japanese in that it has maximally one lexical H-tone (or 'pitch accent') per word, but it is assigned to the mora, which means that a monosyllable like [ei] can have H either on the first mora ('dog') or on the second ('dogs'). Unaccented moras have L-tone. The location and presence of the H pitch accent in Somali largely signal morphological and syntactic, as opposed to lexical information. In addition to marking number in some nouns by its location, the H pitch accent is deleted in WH-phrases, for instance, as in [ei geé] 'which dog'? (Hyman, 1981). Other languages have a number of word melodies, like H, HL, LHL, that are specified along with the vowels and consonants for each word. The way tone strings distribute themselves over the TBUs of the word formed a significant motivation behind the development of autosegmental phonology, whose essential claim is that more than one segment on one tier may correspond to a single unit on the other. This is illustrated for the Mende words in (5) (from Leben, 1978). All three words happen to have the LH word melody, but because of the different numbers of syllables, their syllabic tone patterns come out as 'rise' for (3a), 'low-high' for (3b), and 'low-high-high' for (3c). This is achieved by assuming that the first tone of the melody associates with the first syllable and subsequent tones with subsequent syllables, if there are any, that leftover tones are associated with the final syllable and leftover syllables are associated with the last tone. (Not all the words of the language follow precisely this pattern of association.)

```
(3) a. mba          b. navo          c. ndavula
       |\               | |                | |/
       L H              L H              L H
       'rice'           'money'          'sling'
```

Tone grammars can be quite complex. There is a general tendency for tones to be pronounced later than the syllables with which they are lexically associated, which leads to a wide variety of rules for spreading and moving tones rightward. Also, in the way they regulate the associations of tones, grammars may effectively ignore one of the tones, leaving empty TBUs to be filled up with a 'default tone' (Hyman, 2001). Both features are illustrated by Nochixtlán Mixtec, where a final H-tone in morphemes associates with the rightmost mora of the next word. At the same time, all moras must be provided with tones. In (4a), the tone of [kasi^{H}] 'eat' associates with the last syllable of [lana^{MH}]. The preceding H of the verb prefix [nā^{H}] will fill up the first syllable of [lana^{MH}], while the initial three empty syllables are filled with default M (not shown). The final MH of [lana] are deleted. The resulting pronunciation is (4b) (McKendry, 2013).

```
(4) a. nã          kasi lana        b. nā̃ kāsī láná
                                       'May the child eat'
       H           H   MH
       SUBJUNCTIVE eat child
```

Many two-tone systems in Bantu are underlyingly H vs Ø, as opposed to H vs L, whereby Ø is filled in with L on the surface. The motivation for such privative analyses is provided by the presence of rules that refer to H and the absence of any rules that refer to L (Hyman, 2001). For instance, no morpheme could consist of, contain or assign L, while for H at least one of these operations exists. Whereas H is typically subject to distributional restrictions, for instance, in never occurring in nonperipheral syllables in the underlying word or in being banned from final syllables in the phrase on the surface, the distribution of L can be expressed only in terms of where H does *not* appear. Languages may have the same tone as a default tone and an underlying tone. In Nochixtlán Mixtex, an L-tone between H and M is raised to M, causing HLM to be HMM on the surface. If the third position is empty, however, a preceding HL sequence remains intact, even though an M will appear as a default tone on the surface, giving HLM (McKendry, 2013). If there is a default tone, it is most likely to be L in a two-tone system and M in a three-tone system, but these patterns are not exclusive.

Sentence Prosody

The prosody of the sentence is determined by its prosodic phrasing and its tonal structure. The prosodic phrasing consists of a hierarchically structured set of phonological constituents (Selkirk, 2011; Nespor and Vogel, 1986; Hayes, 1995). The tonal structure has different sources. Boundary tones come with one or more of the phonological constituents, intonational pitch accents, and any lexical tones that are introduced by the words.

The Prosodic Hierarchy

In (4), an example of a prosodic representation is given of an English sentence, together with frequently used symbols. The boundary tones are subscripted for the phonological constituent they come with, in this case the IP.

H-tone, pronounced after the pitch accent on *cooks*. Boundaries of this type often are felt to correspond with a comma in writing. The utterance, finally, roughly corresponds with the intuitive notion of spoken sentence. There are three phonological phrases (*Too many cooks*, *spoil*, and *the broth*), two intonational phrases (*Too many cooks* and *spoil the broth*), and one utterance (*Too many cooks spoil the broth*).

The higher ranking phonological constituents are less predictable from other aspects of the linguistic structure than the lower ranking ones. The most important factor for the phonological phrase and beyond is the syntactic structure, but great length of constituents may lead to the insertion of constituent breaks. For instance, while *Swans like to swim in the river* may well be one IP, a replacement of *Swans* by *Hippopotamuses* is likely to cause a separate IP to arise for the subject. Conversely, a short length may lead either to restructuring, the merging of constituents that would be expected to be separate

(5)

The entire structure above the syllables is assumed to determine how these syllables are rhythmically organized, just as the structure above the foot does this for feet, and so on. The constituent that dominates the foot is the phonological word. In (4), each foot happens to be dominated by a phonological word. A diagnostic for the phonological word in Germanic languages is syllabification: within this constituent, consonants syllabify as onsets with vowels to their right. The phonological word may be smaller or larger than the morphological word. In Germanic languages, each lexical constituent is a separate syllabification domain (e.g., English *cat's eyes* syllabify as [kæts.aɪz], not as *[kæt.saɪz], cf the single phonological word *capsize*). Clitics are morphemes that are included in a following or preceding phonological word (e.g., English *What is he* [wɒt.si] *saying?*). The phonological phrase may determine the distribution of accents, favoring first and last accents. Although, *Too many*! will have two accents, *Too many* COOKS is likely to lose the pitch accent on *many*.

The term 'stress shift' is applied to cases in which such rhythmic deaccentuation leads to the sole presence of a pitch accent on a foot with secondary stress, as in JAP*a*NESE, but JAP*a*nese FUR*n*iture (Gussenhoven, 2011). The intonational phrase typically comes with *boundary tones* at its edges. The intonational phrase *Too many cooks* in (4) ends with an

on the basis of the syntax, or cliticization, the inclusion of a short syntactic constituent into a lower ranked constituent than it would have formed by itself if syntax were the only determinant. An example of restructuring occurs in verb–adverb combinations in American English (Nespor and Vogel, 1986, p. 178). If the adverb is a single phonological word, it is likely to merge with the verb into a single phonological phrase. Thus, in *Rabbits reproduce quickly*, the words *reproduce* and *quickly* will combine in a single phonological phrase, while in *Rabbits reproduce quickly and quietly* the verb will retain a phonological phrase to itself. In some varieties of English, the difference is shown by the pronunciation of *reproduce*. In the first example, a pitch accent will occur on *re-*, but in the second, there will (also) be one on *-duce*. In verb–object combinations, a similar situation exists. Thus, *spoil the broth* may form a single phonological phrase, as shown by varieties that allow stress shift in verb–object combinations where the object is a single phonological word. The pronunciation of the verb in MAIN*tain* OR*der* will then contrast with that in OR*der to main*TAIN. In *We need to maintain order and discipline*, however, the pronunciation *MAIN*tain* is ungrammatical in those same varieties. In English, cliticization applies to pronouns and auxiliaries, for instance, as illustrated by the pronunciation of *What is he* in the previous paragraph. There is no consensus on how many

prosodic constituents there are across the languages of the world and terminology will vary. Japanese has an *accentual phrase*, which seems to lie halfway between PW and the phonological phrase, also referred to as a *minor phrase*, while a *clitic group* has been claimed for Italian and English, for instance.

Preboundary lengthening refers to the phenomenon that the last syllable of a higher phonological constituent is longer than a medial syllable, an effect that is larger as the constituent rank is higher. At the level of the phonological word in English, it is responsible for the difference in pronunciation between *sin tax* and *syntax*, where [sɪn] in the first structure is longer than in the second. And at the higher end, the insertion of an intonational phrase boundary after *go* in *Let's go and have dinner* will considerably lengthen *go* (e.g., Beckman and Edwards, 1990; Wightman et al., 1992; Gussenhoven and Rietveld, 1992; Byrd et al., 2006).

Initial strengthening is the more careful pronunciation of initial segments of a phonological constituent. For instance, the utterance-initial [t] in *Tie it up*! is likely to have a wider area of contact, a longer period of aspiration (a longer, positive Voice Onset Time) than the word initial one in *Stronger ties*, while the same will be true for the latter [t] relative to the foot-initial one in *Valentine* (Cho and Keating, 2001; Keating et al., 2003; Cho et al., 2007).

Finally, the constituents in the prosodic hierarchy often define the context of segmental restrictions. For instance, syllable final plosives and affricates are voiceless in Turkish; syllable final obstruents are voiceless in Dutch; within Italian prosodic words, intervocalic [z] occurs to the exclusion of [s]; and in Kimatuumbi, all vowels are shortened except for any long vowel that ends up in the last word in the phonological phrase (Nespor and Vogel, 1986).

Tone Structure

The tones in a sentence have three sources. First, there are the tones that come with the morphemes in the structure (i.e., the lexical tones). Second, phonological constituents like the intonational phrase and the phonological phrase may begin or end with boundary tones, and third, intonational pitch accents may occur on certain words. Boundary tones will signal the prosodic phrasing of utterances, and since this largely reflects the morphosyntactic structure, will play a crucial role in parsing speech (Cutler et al., 1997; Carlson, 2009; Pannekamp et al., 2005). In addition, there may be a choice of boundary tones, in which case, they signal discourse meanings like 'statement,' 'finality,' 'question,' and so on. Japanese sentences, for instance, have tones from the first two sources (Pierrehumbert and Beckman, 1988). In addition to the lexical pitch accents, the accentual phrase invariably begins with an LH melody, notated LαHα, and the utterance is ended by either an L, signaling declarative meaning, or H, for interrogative meaning. Most European languages derive their tones from the second and third sources, in each case providing a large number of choices, giving a wide variety of discourse meanings (e.g., Pierrehumbert, 1980; Grice, et al. 2005; Frota, 2000; Ladd, 2008; Gussenhoven, 2005; Chen et al., 2007). Swedish and Norwegian have tones from all three sources (Kristoffersen, 2000; Riad, 2013), as do Northern Bizkaian Basque (Hualde et al., 1994), Belgrade Serbian (Smiljanić, 2002), and the dialects in Germany, Belgium, and the Netherlands known as Central Franconian (*Mittelfränkisch*) and Limburgish (e.g., Gussenhoven and Peters, 2004) (cf van der Hulst, 1999). There is considerable variation in the proportions of intonational and lexical tones. For Standard Chinese, the existence of an interrogative utterance boundary tone has been claimed (Duanmu, 2007), where all other tones are lexical. At the other extreme, there is the existence of a pitch-accent-marked focus governing words like [o] 'even' in Bengali, which otherwise only has intonational tones (Lahiri and Fitzpatrick-Cole, 1999). When all the tones have been sequenced into a string, there may be rule-governed assimilations or deletions of tones, after which the surface representation is converted to tonal targets (Pierrehumbert, 1980). Interpolations may be linear or may have somewhat-convex or convex shapes (Niebuhr, 2007; Barnes et al., 2013).

In (5a), the tones for the Japanese word for *New Zealand* are illustrated. The word has a lexical pitch accent (LH) on the penultimate syllable; the declarative tone is notated Lʊ. Together with the initial boundary tones of the accentual phrase, these tones will associate with the available moras in the word, and the target of each tone is indicated by a bullet. (Many speakers avoid rising pitch on a single syllable, as in *nyuu* in (5), replacing it with high pitch.) In (5b), the Portuguese equivalent is shown, which will have a prenuclear H* pitch accent on the stressed syllable [no] and a nuclear H + L* pitch accent in the stressed syllable [lã], where the leading H-tone is pronounced on the preceding syllable, followed by a boundary L-tone of the intonational phrase (Lɪ). In (5c), the Venlo Limburgish word is shown, which illustrates a case of tone assimilation. The language has a lexical H-tone (Accent 2), which assimilates to L if it occurs on the last mora of the intonational phrase and is immediately followed by Lɪ. Tone bearers are the sonorant moras in accented syllables ([zee] in (5c)) and IP-final syllables ([lɑnt] in (5c)), which require a tonal association. This is the reason why lexical L spreads to the available second mora in [zee], which has been left unused by the H*, which associates to the first mora of [zee]. The phonetic reflex of the combination of lexical L and the final boundary Lɪ is a leveling off or slight reversal of the falling pitch movement, as shown in (5c), which contrasts with the straight fall used for Accent 1.

Thus, just as lexical tones are subject to a tone grammar, so too are intonational tones. The distinction between lexical and postlexical phonology (*see* Phonology) is relevant in that no lexical tone rules can affect intonational tones, but as example (6c) shows, postlexical rules can affect both lexical and intonational tones. As a further example, Japanese has rules that govern the priority of tonal associations in cases in which there are more tones than moras, such as when a [LαHα HL Lʊ] tone string (see (6a)) needs to be pronounced on a monomoraic accented word like [ka˥] 'passable school

grade' or a bimoraic one like [hai˥] 'yes' (Gussenhoven, 2004, Chapter 10).

The Expression of Focus

Languages frequently exploit prosodic structure for the expression of *focus*, the marking of information status in sentences (REF Information structure/focus; *see* Information Structure in Linguistics). Frequently, this occurs through the compression of the pitch range over words after the focus constituent. In European languages, this is achieved by the deletion of pitch accents after the focus, with conditions for deletion varying from language to language (Vallduví, 1992; Swerts et al., 2002; Ladd, 2008). In other languages, the words after the focus constituent have reduced pitch range, but the tonal structure remains intact, meaning that lexical distinctions in Chinese are retrievable postfocally. It has been suggested that postfocal compression is an areal feature of Europe and North Asia (Xu et al., 2012). Different meanings or categories of information structure are discussed in Lee et al. (2007). For many languages, an understanding of the prosodic expression of focus structure is impossible without considering the syntactic constraints on focus, because these may implicate the distribution or identity of boundary tones or lexical tones (cf Aboh et al., 2007; Fiedler and Schwarz, 2010). Still, in many languages, information structure may show no prosodic effect of prosody at all (e.g., Zerbian, 2007).

Supreme Courts

Charles R Epp, University of Kansas, Lawrence, KS, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article summarizes multiple features of supreme courts in common-law and civil-law countries: their characteristics, decision-making processes and dynamics, and relations to other governmental institutions and important organized interests and parties in society. The survey is limited to courts of final appeal that take cases from lower courts within national judicial systems (thus, constitutional courts that take cases only on referral from other governmental branches are not included in this definition). Particular, but not exclusive, attention is devoted to the growing policy-making role of many supreme courts in recent decades, to significant limitations on judicial power, and to mechanisms used by governments in many countries to compel their supreme courts to defer to governmental policies.

Supreme courts are courts of final appeal within national judicial systems. Civil-law countries have, effectively, three (or more) separate court systems covering different areas of the law; there are separate institutions at the head of each, of which only the supreme civil court is called a 'court.' Federal systems commonly have, along with a national supreme court, separate supreme courts for their states or provinces. The development of supranational courts (e.g., the European Court of Justice) further complicates the matter, as these have become the courts of final appeal on some matters. Among these many institutions that arguably function in one way or another as 'supreme courts,' this article focuses on national, not supranational or subnational, courts, and on courts whose cases arrive principally by way of appeal from lower courts.

Over the past 30 years, scholarly interest in these courts has grown significantly as globalization, democratization, human rights movements, and a weakening of centralized governmental power have encouraged many supreme courts, in a wide array of countries, to intervene increasingly frequently and actively in the policy process (Alter, 2001; Domingo and Sieder, 2001; Epp, 1998; Helmke and Rosenbluth, 2009; Henkin and Rosenthal, 1990; Keller and Stone Sweet, 2008; Tate and Vallinder, 1995). For this reason, many observers have contended that strong and independent supreme courts play a key role in fostering the conditions for constitutional democracy, the rule of law, the protection of individual and minority rights, and economic development. These are heavy burdens to bear, and the capacity of supreme courts to achieve a wide range of policy goals is often exaggerated. Although supreme courts are not without significant influence, their power is constituted and thus also limited by their countries' particular political, social, and economic structures. Nonetheless, the conditions favoring active policy intervention by supreme courts show no signs of abating, and scholarly attention to them is likely to increase.

Institutional Structure

The Main Types

Supreme courts take a wide variety of forms and are related to other political institutions in a variety of ways, but they nonetheless fall within two main types, reflecting the broad division between the common-law and civil-law traditions (see Legal Systems, Classification of; Common Law; Civil Law). In common-law countries, a single national supreme court has general jurisdiction over a wide range of cases in virtually all areas of the law arising in lower courts. These courts are recognized as *de facto* law-making bodies (through their development of case law), and traditionally have been valued for their roles in checking executive discretion and lending coherence and consistency to their country's case law. They exercise these roles almost exclusively in cases arising out of concrete disputes between two or more parties; the losing party in a lower court may appeal the decision to a superior court, and a small proportion of these appeals ultimately reaches the country's supreme court, where review, in theory, is confined to disputes over law (and not facts) (see Appeals: Legal). This model is found today in countries throughout the former British empire, particularly in the United States, Canada, Australia, India, Ghana, Kenya, Nigeria, as well as South Africa.

In some common-law countries, particularly the United States and countries following its model, the supreme court possesses the power of judicial review to strike down legislation as unconstitutional, but typically only incidentally to the resolution of disputes between two or more parties (a system known as 'concrete review') (see Judicial Review). In other common-law countries – those with parliamentary sovereignty based on the British model – the supreme court has no such power but nonetheless exercises relatively broad authority to check administrative discretion. Following the enormous symbolic influence of the US Supreme Court's attack on racial segregation and its creation of new individual rights in the 1950s and 1960s, some supreme courts in common-law countries, particularly Canada and India, shifted markedly from the British to the American model by increasingly exercising the power of judicial review, particularly in the area of individual rights (Epp, 1998; Knopff and Morton, 1992). Under the growing influence of European law, even the Appellate Committee of the House of Lords, Britain's supreme court, has been legislatively reformed as a new Supreme Court, and its decisions appear to be edging toward a frank exercise of judicial review, a trend that is likely to be reinforced as Britain's new bill of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86115-2

rights gains authority (Blom-Cooper et al., 2009; Dickson, 2007).

Civil-law systems, by contrast, have been influenced by the French Revolution's efforts to limit the power of courts and to foreclose the development of an independent, powerful, and active judiciary headed by a single supreme court. Consequently, the supreme judicial power in many civil-law countries is divided into three (or more) distinct institutions, each with a specialized jurisdiction (Jacob et al., 1996; Merryman, 1985). Thus, in France, the ordinary judiciary, which is headed up by the Court of Cassation, traditionally has been strictly forbidden from exercising judicial review or in any other way challenging legislative or administrative acts. The value of some mechanism for checking administrative acts was quickly recognized, however, resulting in the creation of a separate administrative court, the Contentious Section of the Council of State (hereafter, the Council of State), which now functions as the supreme court for the administrative court system. With the growing interest in constitutionalism after World War II, many civil-law countries added a separate constitutional court with the power of judicial review over legislation, reflecting the belief that the ordinary supreme court was insufficiently statesmanlike, too conservative, or too tied to a prior regime to give meaningful effect to constitutional provisions (Cappelletti, 1989, p. 145; Stone Sweet, 2000) (see Constitutional Courts). In countries in which the con-stitutional court decides challenges to existing laws, that court and the ordinary supreme court have at times developed sharply conflicting interpretations of the validity of particular laws, which has led to significant tensions between these courts (see, e.g., Krug, 1997). The civil-law model – with multiple courts of last resort – has been adopted throughout much of Europe and in many parts of Africa, the Middle East, and Latin America.

The strength of the pressures favoring active supreme court participation in the policy process is evident in the history of the French system. The French Court of Cassation originated as a legislative tribunal with power only to quash incorrect judicial interpretations of law, but over time it adopted a forthright appellate function and eventually was formally converted into the ordinary court system's supreme court; it has since engaged in significant judicial policy making (Merryman, 1985) (for parallels in Britain, see Stevens, 1978). Similarly, although the Council of State is not a part of the regular judiciary, it has evolved to a position of independence within the administrative branch, adjudicates the legal claims of individuals against the state bureaucracy, exercises judicial review over administrative regulations (which constitute a substantial proportion of French law), and has served as a model for supreme courts elsewhere (Brown and Bell, 1993; Merryman, 1985). Although formally there is no doctrine of *stare decisis* (the rule of precedent) in civil-law systems, in practice the decisions of the Court of Cassation and the Council of State gain wide adherence in lower courts and constitute a body of 'jurisprudence' that is similar in many ways to case law (Merryman, 1996).

The institutional structures of supreme courts in Latin America mix elements of the US and French models (see, e.g., Garcia, 1998; Navia and Rios-Figueroa, 2005). Thus, most Latin American countries have a single supreme court with the power of judicial review and with general jurisdiction over appeals from a variety of ordinary courts, but many deny to the inferior courts the power of judicial review. Even the supreme court's power of judicial review in most of these countries is limited to suspending the application of a law in a particular case, not invalidating the law itself. Some countries in the region follow the French model by denying the supreme court jurisdiction over the administrative courts; in others, the supreme courts hear only constitutional issues that are referred by the legislature. Judicial reforms of the 1980s and 1990s moved some Latin American countries closer still to the US model. Thus, in a 1994 reform the Mexican Supreme Court gained the power of judicial review, its justices gained a 15-year tenure, and some of the Court's decisions now have the force of precedent (Rios-Figueroa and Taylor, 2006).

Agenda Setting, Workload, and Internal Structure

The workload of many supreme courts has increased tremendously in recent years, providing significant opportunities for creative judicial policy making. To better manage rising caseloads, some countries have created intermediate appellate courts and have granted their supreme court significant discretion over which cases to decide. Such reforms acknowledge and enhance the policy-making role of the supreme court, and courts that have this discretion typically use it to expand their policy-making activities by building a coherent agenda that commonly has focused on constitutional issues (Pacelle, 1991). Granting the supreme court discretion over its judicial agenda is more typical of common-law than civil-law systems, as appellate review traditionally has been viewed in the former as an extraordinary resort, whereas in the latter it is viewed as a regular aspect of the judicial process (Damaska, 1986; Shapiro, 1981). Countries that have not granted discretion over case selection to their supreme courts – like India and France – are virtually forced by rising caseloads to expand the number of judges on the court; this is often accompanied by a division of the court into several panels (or 'chambers' or 'benches') specializing in different areas of the law.

Supreme courts differ, too, in how decisions are issued. The decisions of common-law supreme courts typically report significant disagreements among the deciding justices. Some, like the supreme courts of Canada and the United States, issue a single majority opinion along with dissenting opinions; others report separate (*seriatim*) opinions written by each of the justices. Civil-law courts, by contrast, commonly present a public face of consensus that conceals politically motivated disputes among the judges. Generally important decisions are published, but this varies too.

These various internal structures provide senior supreme court justices with different opportunities and constraints for strategic influence. Thus, in courts that are divided into separate panels, the chief justice may influence outcomes in particular cases through the exercise of authority to assign justices and cases to particular panels. In courts that meet as a whole, as in the United States, the chief justice or the senior justice in the majority similarly may influence case outcomes by exercising authority to assign the responsibility for writing the majority opinion (see, e.g., Epstein and Knight, 1998, pp. 125–135).

Judges may also manipulate the timing and publication of decisions for strategic effect. Thus, in some cases Israel's High Court of Justice has influenced the Israeli government's anti-terrorism policies by communicating behind-the-scenes threats to rule against the government unless policy is changed; some progovernment decisions in response to changed policy thus mask a more complex behind-the-scenes interaction (Hofnung and Margel, 2010).

Supreme Courts in the Political Process

Political Influences on Supreme Courts and Their Legitimacy

Supreme courts, while forthrightly legal institutions, are influenced by both legal norms and the political process, but the ways in which they are political, and the nature and paths of political influence, vary considerably. Although countries have adopted a wide array of constitutional and statutory provisions aimed at striking a balance between judicial independence from undue political manipulation and judicial responsiveness to widespread popular values, the effects of these measures are strongly shaped by several key factors related to the broader structure and distribution of political and organizational powers in each society.

First, the more centralized governmental power is, particularly in the executive, the greater the possible degree of direct manipulation of the supreme court by officials in these other institutions is. At one extreme, military coups or the exercise of emergency powers by governing regimes are commonly associated with sharp limitations on the authority of a country's supreme court and direct manipulation of the court by the regime (Halliday et al., 2012; Helmke, 2005; Tate, 1993). At the other extreme, in countries in which governing power is divided by a federal structure, an American-style separation of powers, or both, the paths of influence on the supreme court are more attenuated, affording the supreme court greater room for maneuver (Helmke and Rosenbluth, 2009). Between these ends of the continuum lie many intermediate instances. Thus, the supreme courts of Latin America vary considerably in degree of control by the executive and level of judicial intervention in key policy disputes (Helmke, 2005; Hilbink, 2007; Couso et al., 2010). Nonetheless, even supreme courts in pluralistic systems – for example, the United States and Canada – are influenced by the national governing coalition and may be active in many policy areas yet rarely challenge directly the key policies favored by that coalition (Whittington, 2005).

Second, political influences on supreme courts are conditioned by the degree of pluralistic conflict over selection of justices and the degree of diversity in the pool from which justices are drawn (Malleson and Russell, 2006). At one extreme, in a pattern more typical of common-law than civil-law countries, are courts whose appointment processes are subject to open political conflict between competing factions and whose justices are drawn from a relatively diverse population that includes politicians, government officials, and law professors. Thus, in the United States, the constitutional requirement for Senate confirmation of nominations made by the president has afforded the opportunity for open, pluralistic conflict over appointments to the Supreme Court (Yalof, 1999). At the other extreme are systems that insulate appointment processes from popular pressure and that draw judges from an insular elite, a pattern typical of civil-law countries. In some civil-law countries, the judiciary is largely self-regulating; judges are selected by competitive examination after receiving specialized legal training, and they advance through the judicial hierarchy on the basis of seniority and the approval of superior judges. In other civil-law countries, the executive dominates judicial recruitment and promotion to the supreme courts. Often, the two factors are found together, resulting in highly insular supreme courts.

For instance, in Chile the Supreme Court annually evaluates and ranks all of the country's judges, and appointments to the Court are made by the executive from a short list of nominees selected by the Court itself from among the lower judiciary; the system discourages the development of diversity of opinion and creativity within the judicial ranks, and, as a consequence, the Court has remained very quiescent over most of its history (Hilbink, 2007). Although the differences between civil-law and common-law patterns of appointment to supreme courts thus loom large, the dichotomy does not account for all variations. In the common-law world, the process of appointment to the US Supreme Court is notoriously open and conflictual, while for the British higher judiciary it is highly insular. In France, judges on the Court of Cassation are drawn exclusively from inferior courts; by contrast, members of the Council of State are drawn not only from inferior administrative tribunals but also from the administrative bureaucracy and academia (Brown and Bell, 1993, pp. 78–80). In general, the insularity of the recruitment process in continental Europe appears to be gradually eroding, with potentially significant implications for the judicial role.

Third, the degree of popular legitimacy of supreme courts and the nature and diversity of external coalitions of support for them place constraints on direct manipulation of these courts by other governmental officials. Some supreme courts have gained significant popular legitimacy, while others remain relatively unsupported. Support from the organized bar and other groups in civil society has often played a critical role in building these coalitions of support (Epp, 1998; Halliday et al., 2012). Even in authoritarian regimes, supreme courts have sometimes gained considerable support and leverage from broad external coalitions of popular support (see, e.g., Ginsburg and Moustafa, 2008; Lopez-Ayllon and Fix-Fierro, 2003). Judicial legitimacy, ironically, may be cultivated by courts themselves through active intervention in the policy process that attracts external coalitions of support (Gibson et al., 1998). Where coalitions of support are diverse and politically strong, they have played key roles in protecting supreme courts against measures aimed at curbing their power. This is clear, for instance, in comparing the limited success of attacks on the US Supreme Court prior to 1937 (Ross, 1994) with the Gandhi government's relatively greater influence over the Supreme Court of India in the 1970s (Baxi, 1980; Epp, 1998). In general, judges in common-law countries tend to be accorded relatively high status and respect, while the civil-law tradition has cultivated a deeply entrenched distrust for the judicial role and for judges

(Merryman, 1996). But beginning in the 1990s, many Latin American countries experienced growth in support for active judiciaries and enacted reforms to enhance judicial independence and power (Couso et al., 2010).

Although the various factors just summarized are conceptually distinct, they are mutually reinforcing in practice. Governing systems in which political power is decentralized have tended to accord greater symbolic status to their judges, particularly to their supreme court justices; develop pluralistic and even conflictual appointment processes that select justices from a diverse population; and cultivate broad coalitions of support around their supreme courts. Moreover, their supreme courts have tended to be relatively actively engaged in the policy process. By contrast, governing systems in which political power is centralized have tended to accord their judges, even their supreme court justices, the lowly status of legal bureaucrats and to select these justices through an executive-dominated process from highly insular pools of legal professionals. As a consequence, these courts have developed highly formalistic decision processes that yield politically acquiescent decisions and rarely cultivate support in the broader population. The latter extreme is exemplified by the insular judicial bureaucracies of some Latin American countries that have few sources of popular support – a pattern that is surely compounded by the effects of economic inequality on the degree of organizational pluralism in civil society (see, e.g., Hilbink, 2007).

The Growth in Policy Intervention by Supreme Courts, and the Limits of Their Power

Supreme courts, particularly in governing systems in which political power is not highly centralized, have increasingly intervened in the policy process in recent decades, particularly with regard to individual rights, environmental protection, and social welfare. The literature on these developments is large and growing (see, e.g., Couso et al., 2010; Dickson, 2007; Epp, 1998; Ginsburg and Moustafa, 2008; Hirschl, 2004; Tate and Vallinder, 1995; Widner, 2001).

Several partially conflicting strains have developed in these studies. One is over the degree to which high courts should be viewed as frankly political institutions. On this topic, some scholars have argued that supreme court judges are straightforwardly political. The 'attitudinal model' posits that justices' decisions directly reflect their political attitudes; this theory, although originally based on studies of the US Supreme Court (Segal and Spaeth, 1993), has been applied elsewhere as well (Morton et al., 1995). A closely related theory posits that justices' decisions are strategic, meaning that justices try to enact their political preferences but must modify, check, or restrain these desires in light of the expected responses of other actors or institutions (see, e.g., Epstein and Knight, 1998; Maltzman et al., 2000). This, too, has proved fruitful in studies of judicial policy making worldwide (see, e.g., Helmke, 2005; Hirschl, 2004). Other scholars, by contrast, favoring a theory sometimes labeled 'new institutionalism,' posit that justices' decisions are influenced by institutions, understood as organizational norms, rules, and structures, both among formal governmental structures and in the structure of civil society (see, e.g., Clayton and Gillman, 1999). Thus, legal assumptions establish the foundations and boundaries of judicial decision making and thereby constrain judicial decisions (Bartels, 2009; Dickson, 2007; Gillman, 1993); and the institutional relationship of the supreme court, the executive, and the legislature shapes the range of discretion available to the court (Navia and Rios-Figueroa, 2005). This institutionalist perspective appears in many studies of supreme court decisions worldwide (see, e.g., Couso et al., 2010; Epp, 1998; Ginsburg and Moustafa, 2008; Perry, 1991).

The extent to which supreme courts are capable of effecting substantial changes in governmental policy, and whether the policy effects are mainly egalitarian or antiegalitarian, remains a matter of dispute. It is clear that supreme courts have no enforcement authority of their own and thus depend for implementation of their decisions on the actions of public officials, private individuals, and organizations. On this basis, Gerald Rosenberg (1991) has argued that policy reform decisions of the US Supreme Court have led to actual reforms only in very limited circumstances, particularly when they are aided by sympathetic officials or a sympathetic population, or are subject to implementation by market forces. Michael McCann (1994), however, has shown that judicial decisions provide strategic resources that may be used by social movements, organized groups, and public officials to substantial effect (albeit often in ways unanticipated by the judiciary) (see Law, Mobilization of). These competing perspectives share the core observation that supreme courts depend on external actors to carry out their decisions, and this support varies. In the absence of organized support, court decisions often have little force, but in its presence they may produce considerable policy change (see, e.g., Epp, 2009; Gauri and Brinks, 2008). Taken as a whole, the increasing policy intervention of supreme courts, and of courts in general, has contributed to the 'judicialization' or 'legalization' of policy and admin-istrative processes, but whether this has contributed to democratization or has benefited the least well off varies considerably (Brinks, 2008; Couso et al., 2010; Epp, 2009; Tate and Vallinder, 1995).

The State of Social Scientific Research on Supreme Courts

Research on supreme courts has advanced remarkably in the past 20 years. Scholars have made careful studies of a wide range of courts that previously had been ignored and have developed sophisticated quantitative databases of decision-making patterns in some of these courts. Additionally, research agendas are increasingly based on social scientific theories and thus increasingly attempt to explain rather than merely describe. Yet important gaps remain. Most of the existing social scientific research on supreme courts has focused on a handful of highly active courts, while many other courts, particularly the supreme courts of cassation in the civil-law world, have been largely ignored. Most of the research has focused on the conditions shaping supreme court decisions; little has been done on the policy consequences of these decisions, even though it is widely recognized that decisions are often implemented only in part, if at all. Finally, although research on

supreme courts in many parts of the world has expanded, only a few truly comparative studies have been done.

Nonetheless, our understanding of supreme courts has grown. The body of social scientific research suggests both that supreme courts may contribute to the broader goals that many observers in recent years have pinned on them – the protection of individual and minority rights and the cultivation of constitutional law more generally – and that the extent to which they support these goals is conditioned by a range of factors, particularly the degree to which political power in the governing system is centralized and the degree to which these courts enjoy popular legitimacy and coalitions of support among civil society organizations.

Abstract

Surveillance and privacy are mutually exclusive: if one increases, the other decreases. After defining these terms and their relation to each other, this article introduces key concepts in the field of surveillance studies, followed by a discussion of classical forms of surveillance and privacy invasion, namely, forms of visual surveillance. The second half of the article departs from the surveillance of individuals to new technological trends that represent new challenges to privacy concerns and the social sorting of populations through software algorithms.

Surveillance

Surveillance is a complex issue that has sparked a number of definitions. Because we have to start somewhere, we defer to two intellectual authorities in the field, Lyon (2007) and Marx (2012), who define surveillance in general terms outside the risk and security discourse in which it is often applied. Lyon (2007, p. 14) defines surveillance as follows:

> (...) the focused, systematic and routine attention to personal details for purposes of influence, management, protection or direction. Surveillance directs its attentions in the end to individuals (even though aggregated data, such as those available in the public domain, may be used to build up a background picture). It is focused. By systematic, I mean that this attention to personal details is not random, occasional or spontaneous; it is deliberate and depends on certain protocols and techniques.

Marx applies a similar individually focused angle to his definition:

> At the most general level surveillance of human (which is often, but need not, be synonymous with human surveillance) can be defined as regard or attendance to a person or to factors presumed to be associated with a person.
>
> Marx, 2012, p. xxv

While outlining various more detailed subfields of surveillance, Marx maintains a relatively strong focus on one individual or group attending to another individual or group. Thus,

> some common classificatory notion can be applied. In the case of surveillance social structures, for example, we can identify the *surveillance agent* (weather as watcher/observer/seeker/inspector/auditor/tester), while the person about whom information is sought or reported is the *surveillance subject*.
>
> Marx, 2012, p. xxv, emphasis in original

Inherently linked to these definitions is privacy, which we will discuss in the context of surveillance. The two terms can almost be understood as antipodes. The more (or less) surveillance there is, the less (or more) privacy there is. Thus, in an argument about omnipresent surveillance, we commonly speak about the death of privacy.

Privacy

Privacy is commonly seen as a good that needs to be protected against increasing surveillance activities. From this position, privacy is often defined in terms of access to information and control over this access. If surveillance is access to individual or personal information, privacy is the control over this access to information (Rössler, 2001). If we can decide who has access to what information about ourselves, we have full privacy. However, Rössler (2001), a key figure in privacy studies, argues that privacy is not only a desirable good but also a precondition for liberal democracies in which the autonomy to decide over one's own life according to one's abilities is of fundamental importance. To guarantee autonomy, a degree of privacy is needed to protect the individual. If, for example, an employer knew all the private details of an employee's life, such as mistakes in the past, diseases that do not impact the job, and relatives with criminal records, these details would likely influence employment and thus decrease autonomy. Nonetheless, as Rössler acknowledges, privacy in its purest form, i.e., complete control over all personal information, is impossible to achieve given participation in contemporary societies. The state, employers, banks, etc. will always possess some personal information about an individual that is beyond his/her control. Discussing surveillance and privacy is thus a question of balance; how much surveillance is needed to have, For example a functioning government able to provide security, and when is the invasion of the state into the privacy of its citizens unnecessary? Because many governments and governance bodies have a tendency to collect an abundance of data on their populations and thus tip this balance in one direction (Foucault, 2007), different parts of civil society, as well as many of the studies on surveillance and privacy, engage critically with the topic of increasing surveillance and its negative implications on privacy. However, as mentioned, this article approaches privacy in relation to surveillance. Therefore, we only refer to one of what Rössler (2001) calls the three dimensions of privacy. The first dimension, decisional privacy, is concerned, for example, with the freedom to decide what

clothes I put on in the morning. The dimension discussed in this article, informational privacy, is concerned with issues related to access to personal information. The last dimension, local privacy, is concerned with the ability to retreat into personal space, such as one's own home. Elements of this last dimension play a role when discussing visual surveillance in the form of drones.

Surveillance and Privacy Studies

In recent years, a rapidly developing international body of research has sought to explore the various causes, implications, and problems of the contemporary proliferation and intensification of surveillance. The emerging cross-disciplinary field of 'surveillance studies' (Lyon, 2007) has raised a number of critical issues with regard to the intensification and generalization of data gathering, transfer, and analysis in the information age. The resulting critical debates about surveillance fit largely into two complementary and often interrelated categories. The first category – predominant in sociology and urban studies – has sought to challenge the use of surveillance as a powerful tool for social sorting (Lyon, 2003) and is related to concerns of social exclusion and spatial justice (Coleman, 2004). The second category, traditionally predominant in regulatory approaches, has focused mainly on surveillance-related privacy and data protection issues.

In this article, we will touch on both categories. Following an introduction of the concepts and theories that explain surveillance, we introduce surveillance in its classical, human-focused form, drawing on the example of visual surveillance. We then shift our attention to the monitoring of the nonhuman, the foremost of which is urban aspects. As surveillance studies have shown, ubiquitous computing embodied by the various smart campaigns, can have a significant impact on the private even though the focus is not directly on the individual. We outline the social consequences of the various surveillance approaches in our final section.

Competing Concepts

There are different approaches to theorizing surveillance in its multiple facets, applications, and effects. Space does not permit an exhaustive review of the existing approaches, but some of the most important conceptual perspectives on surveillance shall be outlined here to add a more theoretical dimension to our discussion of surveillance and privacy that follows (for a more exhaustive discussion, see, for example, Lyon, 2006).

Surveillance scholars have found a range of conceptual tools in Michel Foucault's theorization of power and governmentality for dealing with the dynamics inherent in contemporary forms of control and regulation. Most notably, Foucault's analysis of disciplinary power, exemplified in his discussion of the Panopticon in *Discipline and Punish* (Foucault, 1977), has inspired a number of empirically and conceptually informed discussions on the normalizing prowess of novel surveillance technologies on individuals and social groups. For Foucault, the Panopticon exemplifies a particular economy of power that characterizes European modernity shaping, working through, and developing from a range of milieus such as hospitals, schools, army barracks, and prisons. The exercise of power in all of these settings implies a specific way of managing multiplicities through techniques of individualized surveillance and normalization.

However, while Foucault's Panopticon paradigm has been used prominently to problematize surveillance in its inherent power problems and implications, additional approaches have been mobilized to create a more conceptually and empirically accurate picture of the actual effects and limits of contemporary surveillance. For example, drawing on Deleuze's analysis of the contemporary shift from a Foucauldian 'disciplinary society' to a postmodern 'society of control' (Deleuze, 1992), various scholars have emphasized the changing modalities and functions of surveillance, from rigid and permanent monitoring and enclosure to more flexible and adaptable forms of regulation and control. Similar insights have been gained from Foucault's recently translated *Security, Territory, Population* lectures, given in 1977/1978 at the College de France (Foucault, 2007). Here, Foucault distinguishes between 'disciplinary' and 'security apparatuses' to capture the differing regulatory dynamics and mechanisms of power in the governing of men and things. A third source of inspiration in counterbalancing the Panopticon paradigm has been found in Michel de Certeau's work, who stresses the microtactics and strategies deployed by individuals and social groups to resist surveillance (De Certeau, 1984). On these grounds, the effects and implications of surveillance on social life (including privacy) have been found to be much more contingent and complex than initially expected.

While Foucault, Deleuze, and de Certeau allowed for the theorization of the effects and implications of surveillance, other theoretical sources have been mobilized to conceptualize the actual internal functioning, logic, and organization of specific surveillance systems. On a rather general level, approaches inspired by Marx and especially Giddens (1985) have portrayed (bureaucratic) surveillance as indeed a defining and constitutive feature of modern capitalist life. More specifically, rooted in an actor-network theory-based line of thinking, as developed by Bruno Latour and Michel Callon (Latour, 2005), various scholars have studied the complex actor networks underpinning and shaping the making of particular surveillance systems. Placing centrally the processes and relationships through which surveillance is conditioned and coproduced, this research has developed an understanding of surveillance in its complex sociotechnical associations and compositions that bring together, and are the result of, a wide range of actors, objects, instruments, intentions, and domains of expertise. This focus also resonates with the longstanding conceptual and empirical interest of Deuleuzian literature in the heterogeneous 'assemblages' of human and nonhuman entities that make up specific milieus or, more specifically speaking, surveillance systems (Deleuze and Guattari, 1987; Haggerty and Ericson, 2000). In terms of privacy, these studies have shown that the implications of surveillance depend on a variety of system-inherent factors, including not only its technical specificities but also resulting from the modalities, dynamic actor

networks, and interacting domains of expertise shaping the system 'in action.'

Visual Surveillance

CCTV

In this section, we discuss one of the most classic themes in surveillance and privacy studies, the CCTV (closed circuit television) camera, and some of its contemporary modifications, such as facial recognition software and drones. The first major boom in the use of CCTV cameras for surveillance and security purposes started in the late 1970s and continued into the 1980s. Particularly in the beginning, CCTV cameras in public space were hailed as a revolution in crime prevention, a claim that failed to manifest itself clearly in empirical data. Although the installation of surveillance cameras often results in a short-term reduction of crime rates, longer follow-up periods show that the cameras' long-term effects in deterring crime have to be interpreted more critically (Welsh and Farrington, 2002; Gill and Spriggs, 2005). Furthermore, a growing range of CCTV evaluations suggest that the efficiency of CCTV strongly depends on which type of crime is being analyzed. For example, CCTV is generally found to be effective in reducing vehicular crimes in car parks, whereas empirical research suggests that CCTV has little or no effect on vandalism and acts of aggression on public transportation systems and in city-center settings. The functioning and impacts of CCTV systems also depend on a variety of system-inherent factors, from collaborations between operators to technical dimensions of the cameras. Nonetheless, the number of cameras in various spaces continues to grow. In the United Kingdom, a country where the CCTV camera enjoys particular popularity, there are an estimated 1.85 m cameras ('The Guardian' http://www.guardian.co.uk/uk/2011/mar/02/cctv-cameras-watching-surveillance). Today, in many countries, high-resolution CCTV cameras can be bought in home improvement shops, and where they can be installed is only limited by national legislation.

Intelligent CCTV Systems

Throughout the 1980s and 1990s, CCTV systems were established and simply continued to exist more or less effectively; however, recent coded technologies have generated a new wave of excitement about CCTV cameras. The availability of large affordable digital storage facilities and fiber-optic cables has made cameras more effective for investigatory proposes and made intelligent networked CCTV systems possible. With continued research on increasingly sophisticated algorithms that can recognize faces, license plates, and even behavior patterns, cameras are becoming exponentially more effective (Graham, 2005). Where there used to be a human agent sitting in front of a wall of screens trying to detect suspicious individuals, code now automates this process. For example, by comparing faces to a database of terror suspects or registered hooligans, the algorithm can sound an alarm once a suspect is sighted or near a strategic facility. Although code is not yet capable of such sophisticated procedures, vast amounts of resources are being invested into the advancement of already existing recognition technologies.

Drones

Another technology that led camera-based surveillance into a new era is the unmanned aerial vehicle (UAV), commonly referred to as drones. UAVs further exemplify the close link between military and civilian surveillance technologies. During the War on Terror and various campaigns of counterinsurgency warfare, drones became increasingly popular and have undergone rapid development in recent years. UAVs are now integral to the warfare practices of technologically advanced armies. What started as surveillance tools soon became armed machines, as the latest versions of the Reaper drone show. Using drones in conflicts, intelligence can be collected and (extraterritorial) attacks carried out without putting pilots in danger (in fact, drone pilots can command their vehicles for a mission over Pakistan from their 'cockpits' in the United States). In their original function as surveillance tools that film or take images from high altitudes, UAVs thus complement satellites but are not bound to a single orbit. Like other developments originating in the military, UAVs soon caught the attention of law enforcement and other civilian agencies. As Graham argues,

> The crossover between the military and the civilian applications of advanced technology – between the surveillance and control of everyday life in Western cities and the prosecution of aggressive colonial and resource wars – is at the heart of a much broader set of trends that characterize the new military urbanism. (…) Fundamental to the new military urbanism is the paradigmatic shift that renders cities' communal and private spaces, as well as their infrastructure – along with their civilian populations – a source if targets and threats.
>
> Graham, 2010, p. xiii

With wars and conflicts being fought increasingly in urban areas, the line between military and civilian surveillance and other technologies is becoming blurred as technologies increasingly serve double functions. Today, UAVs come in all shapes and sizes, ranging from high-tech military drones with wingspans of well over 20 m to small surveillance UAVs that can land on the palm of a hand. Smaller UAVs are becoming increasingly popular with police forces all over the world for obtaining intelligence on armed suspects, groups of protesters, and sports fans or simply for monitoring deserted urban landscapes more efficiently. As mentioned above, UAVs constitute a quickly developing technological field whose development cannot be foreseen. Given their relative low costs and multifaceted functions for surveillance purposes, it is unlikely that drones will disappear from the CCTV/surveillance landscape soon. Combined with high-definition cameras and facial recognition software, drones are the latest high-tech advancement in a surveillance trend that started with the classic CCTV camera in the 1980s. Whereas the usual CCTV camera is stationary, although it may rotate, drones are highly mobile and able to survey many spaces previously unseen by CCTVs. In this context, local privacy, or the freedoms in one's own home, is under threat by the image of a drone hovering in front of a bedroom window (Rössler, 2001). As the technological possibilities increase exponentially, substantial further invasions of

privacy continue to be protected only by a critical civil society and the law, at least in Western democracies.

Computerization of Surveillance

Having outlined the more obvious forms of direct surveillance, we now focus on a more recent surveillance trend beyond the visual that focuses on the monitoring of the nonhuman. Today, we have reached an area of ubiquitous computing, where code penetrates most aspects of life and enables the management of urban environments, including both human and nonhuman objects. The logic of this approach of managing the urban environment is not new, although the first cases were human-oriented. The basic ideas of these current trends date back to the late nineteenth and early twentieth centuries and the first use of punch cards that enabled the structuring of relatively complex data on populations according to different characteristics. A similar logic was utilized by the German police in the late 1970s when *Rasterfahndung* (dragnet policing) was introduced in an attempt to identify members of the *Rote-Armee Fraktion* (Red Army Faction) and other left-wing terror groups. Using a state-of-the-art computer, various available sources of information, such as student loans, insurance, and registration data, were analyzed to obtain a manageable number of locations and suspects assumed to be typical for terrorists. In principle, the process included analyzing large data sets according to set parameters to generate a small number of individualized data.

However, only in recent years have computers and technologies such as GPS tracking and mobile phones become advanced and widespread enough to integrate algorithms into the functioning of everyday lives. Such advancements include RFID (radio-frequency identification) devices, which, by now, are ubiquitous in various trades and have become an unavoidable standard technology. RFID chips store information that is being transmitted via radio frequencies. If the chip comes close enough to a receiver from a few centimeters to hundreds of meters, the information can be read. RFID chips, some of which are not much larger than a grain of rice, can be found in access, food court and student cards, pets and livestock, shipping containers and other cargo, among other things. With a starting cost of just a few pence, the only reason RFID chips are not used even more extensively is data protection concerns, which are why chips have not been put in clothes (the washing machine would automatically know what temperature to use) or directly implemented in humans (this would make it impossible to forget ID cards and easier for police to identify individuals).

This increased computerization of life and dependenc on code led Dodge and Kitchin (2011) to formulate their code/space theory. Some years ago, code supported the functioning of space, as it eased daily operations. If the code broke away or malfunctioned, all operations could, although more slowly and less efficiently, continue. Although this coded space was supported by computing, it did not depend on it. In many instances, this has changed. Today, various spaces depend on code in a way that if the code breaks away, the whole space stops functioning. One example of such a code/space is the modern airport. If the various algorithms that enable check-in, baggage sorting, the functioning of the tower, or the functioning of the planes themselves stop working, the space is no longer an airport, but a chaotic agglomeration of hectic and panicking people. Dodge and Kitchin (2011) provide other examples of how we interact with more banal forms of code/space every day, including diaries in our smartphones, access to our e-mails, the engine of our car managed through the inboard computer, the electronic till of our favorite coffee place, and possibly even the entrance to our office building controlled by a swipe card or RFID chip. All of those examples are spaces that stop functioning in their designed purpose if the code breaks away.

Privacy and Contemporary Smart Surveillance

With the popularized smart city ambitions that are currently symptomatic for the management of urban environments, the idea of code/space is developed to a further extreme. In the context of the hyped smart city technologies, the linkages between increasing computerization and surveillances and privacy become clear. As explained with the example of punch cards and the *Rasterfahndung*, large data sets, are being combined and analyzed. In a process called data mining, linkages within data are made, and new information is extracted. Urban processes are managed on the basis of this new information, possibly resulting in the automation of parts of cities and buildings.

The smart city is currently one of the most prominent urban development technology and is being discussed around the world. Spearheaded by global IT companies, the smart city aims to optimize different aspects of urban space through algorithms. Targeted areas of cities include governance structures, water and electricity grids, traffic and transport, and the emergency services and police. Although part of different sectors, their automations all follow a similar logic, the analysis and interconnection of large quantities of data, including existing data being made available as well as the generation of new data either by digitizing analogous processes, such as electricity meters and sensors on highways or in public transport, or connecting different existing databases. Data are cumulated in vast databases, and once the data are centralized, algorithms can make the city, smart, by rendering the data usable for different optimization proposes, a process called data mining. Such optimization processes include more effective governance function as decisions can be based on the analysis of more data and thus be made faster, optimizing public and individual transport, for example in terms of travel time, or easing access to medical data.

Nonetheless, the data sets these mining algorithms analyze often comprise sensitive and private information. One example is the use of a smart grid, one component of the smart city. Smart grids are one technology experts see as the future of energy production and consumption; they are based on the analysis of the energy patterns of individual households through algorithms and, subsequently, the automation of some electronic appliances through code. The data collected in this process provide insights on individual habits and movement patterns (for example when one takes a shower, leaves the house, watches TV, uses electronic appliances).

The primary function of smart grids is the optimization of energy consumption and increases in alternative energy sources. Although these are honorable ambitions, to get there,

unrepresented amounts of private data are collected with increasing standardization of these technologies. Additionally, these data can potentially serve a secondary purpose; detailed personal information is of considerable value to the advertisement industry, which can create localized and personalized advertisements. This information could be of value to companies interested in the activities of their employees and police who would gain *Rasterfahndungs* capabilities that were unimaginable 30 years ago. Differing from the classical definition of surveillance of Lyon and Marx or the example of the CCTV camera that singles out suspicious individuals, the current trend of surveillance is to collect a variety of data on different aspects and to extract individualized information out of this data pool. Because they are not open or direct, these surveillance functions become blurred to the public eye and are ultimately trivialized by both the surveying agencies and the surveyed population.

Thus, the smart city exemplifies an increasing belief that cities cannot be managed without substantial invention by code and that the complexity of urban lives requires algorithms to regulate them. Indeed, there are arguments that underline the advantage of codes regulating and managing the urban space. However, these developments are rarely discussed with regard to surveillance, and the substantial invasion of privacy is of limited concern. In many contemporary examples, code/space issues of privacy and surveillance are deferred to the legal and institutionalized theme of data protection and detailed accounts on technical solutions against, for example hackers that want to invade privacy and/or abuse private data. What data are really needed in the first place is of lesser concern. Furthermore, with smart city ambitions, it is often automatically assumed that the state is immune to any form data abuse and thus can be trusted with vast amounts of very detailed personalized data, an assumption that was often contested in the past. In the concluding section, some of the implications of this trend are sketched out.

Social/Software Sorting

In this concluding section, we outline the consequences of surveillance, especially the impacts new coded forms of surveillance have on society and privacy. The increasing metamorphosis of space supported by code into code/space creates a situation where it is increasingly difficult, and in some parts impossible, to have control over personal information, who has access to this information, and how this information is being used. This difficultly is evident in our digital traces on the World Wide Web or mobile communication networks, the RFID chips in the cards in our wallets, and the sophisticated CCTV cameras that are watching us.

It is even more difficult for an individual to control his/her personal information with the spatial manifestations of smart cities and related visions based on data mining. By combining different information, code generates new data and information. Because we usually do not know the source information the data mining uses or the workings and capabilities of the code, we no longer have the chance to understand what knowledge about us exists. Linking this back to Rössler's privacy discourse, our autonomy is threatened by this development. In an environment of data mining and networked information, we cannot be certain what our opposite in a meeting might see on his/her screen about us; thus, we lose the ability to control our lives, and the chance of discrimination on the basis of private information grows concurrently. Privacy is increasingly no longer a right.

In addition to its implication on privacy, the computerization of space also enables an increasingly sophisticated sorting of populations along set parameters, as three examples outlined by Graham (2005), Lyon (2003), and Jones (2000) will show.

- Using code to control and regulate traffic flows: Utilizing software tools, road pricing becomes flexible and adaptable, different from the static vignette system some countries apply. Steering congestion through road pricing, the usage of streets during peak hours can become too costly for some at certain times. Although this is a specific example, it relates to the wider issue of managing space and populations, governing at a distance through code (Jones, 2000).
- Using codes to structure the city and manage police patrols: Using software such as geographic information systems (GIS), cities are becoming increasingly digitized. Attributing data to parts of the city, individual streets and so forth, space is being branded, identities are being created, or property prices are being influenced (Graham, 2005). A popular example is the online GIS-based crime mapping tool of the British police (http://www.police.uk/).
- Direct forms of coded exclusion and sorting: Code enables different form of exclusion. Although some of the following could theoretically be achieved, for example using ordinary keys, code eases processes and renders them useable, especially on a large scale. The most banal forms of exclusions include PIN codes, relatively cheap swipe cards, and using biometrics, such as fingerprints or iris scanners, to allow access to buildings. Here different levels of access can be allocated to individuals. The same can be applied to the virtual worlds of inter- and intranets. With the increasing importance of codes for access, the rejection of access privileges can be used in a disciplining way, punishing behavior.

This list could continue. However, the aim is not to produce a complete picture, but to indicate the issues that will arise with an increasing codification of live and space and rapidly advancing computing possibilities. However, the above is not a phenomenon that has emerged because of new possibilities in surveillance, but is rather a reflection of the long-existing desire of various agencies to survey and to manage the surveyed.

> If surveillance as social sorting is growing, this is not merely because some new devices have become available. Rather, the devices are sought because of the increasing number of perceived and actual risks and the desire more completely to manage populations – whether those populations are citizens, employees, or consumers.
>
> Lyon, 2007, p. 20

New code-based technologies support this desire for surveillance and data collection. What gives the development

a novel spin is that the omnipresence of a code, very different from CCTV cameras, begins to blur the line between surveillance and the invasion of privacy. This is especially true when the focus is not safety and security, but the improvement of urban space and the quality of life.

Abstract

This article suggests some basic terms for surveillance analysis. The analysis requires a map and a common language to explain and evaluate its fundamental properties, contexts, and behaviors. Surveillance is neither good nor bad but context and comportment make it so. Topics considered in this article include: a broad definition of surveillance, its strategic and nonstrategic forms, and the traditional and new surveillance. A family of related terms – privacy, publicity, confidentiality, and secrecy – is also considered. The discussion next focuses on characteristics of the social structures that organize behavior, the characteristics of the *means* used, and some value conflicts and social processes seen with the emergent, interactive character of much surveillance behavior.

Queen Elizabeth (1533–1603) introduced modern ideas about the rights of the person including protection against "windows into men's hearts and secret thoughts." In this view, she draws on an English proverb: "the eyes are the windows into the soul" that in turn reflects the biblical claim (Matthew 6: 22–23) that probative looking into another's eyes reveals who they are (questions of deception and validity apart). Queen Elizabeth realized that the dignity of the person requires limits on looking, particularly when coercion and inequality are present, as with state power. Yet as a ruler concerned with the welfare of her subjects she needed information about them, as well as about rule breakers and those who would overthrow her government. Her challenge – juggling the protection of individuals' hearts and secret thoughts and the protection of state security – is one that faces democratic leaders everywhere.

This article suggests some basic terms for surveillance analysis. A map and a common language are required to explain and evaluate its fundamental properties, contexts, and behaviors. The empirical richness of watching and being watched (whether involving the eye or other senses and various kinds of data) and the uses of surveillance results need to be disentangled and parsed into basic categories and dimensions. After offering a brief comment on surveillance studies and a broad definition of surveillance, attention is given to strategic and nonstrategic forms, and traditional and the new forms of surveillance. A family of terms related to surveillance – privacy, publicity, confidentiality, and secrecy – is considered. The discussion next focuses on characteristics of the *social structures* that organize behavior and the characteristics of the *means* used and some *social processes* seen with the emergent, interactive character of much surveillance behavior. I next turn to value conflicts that make surveillance often so controversial. The discussion that follows draws from Marx (2015, and articles at www.garymarx.net) and is informed by the sources in **Table 1**.

What Is Surveillance?

Today's *surveillance society*, as is involves the state, the private sector, and interpersonal relations, brings forth the same paradox faced by Queen Elizabeth noted in the preceding paragraph – whether the National Security Agency's worldwide gathering of metadata on telecommunications, or merchants, employers, and parents watching customers, workers, and children, respectively. In a world where surveillance is seen as both a response to threats and a threat, before asking "Is surveillance good or bad?" we need to ask, "What concepts are needed to capture its basic structures and processes?" Surveillance as such is neither good nor bad, but context and comportment do make it so. The same can be said for the related concept

Table 1 Surveillance essays: names of the new society and its key aspects[a]

The panopticon (Bentham, 1995)
Disciplinary society, the gaze and bio-power (Foucault, 1977, 1998)
Surveillance society, the new surveillance and maximum security society (Marx, 1985, 2015)
Net widening (Cohen, 1985)
Dossier society (Laudon, 1986)
Dataveillance (Clarke, 1988)
Super-panopticon (Poster, 1990)
Society of control (Deleuze, 1992)

Safe society (Lyon, 2007)
Thick and thin surveillance (Torpey, 2007)

[a]A representative, although hardly exhaustive, list.

of privacy. Context refers to the type of institution and organization in question and to the goals, rules, and expectations they are associated with. *Comportment* refers to the kind of behavior expected (whether based on law or less formal cultural expectations) of, and actually shown by, those in various surveillance roles.

While sharing some elements, differences in surveillance contexts involving coercion (government), care (parents and children), contracts (work and consumption) and free-floating accessible personal data (the personal and private within the public) need consideration. Surveillance is a generic process characteristic of living systems with information borders and not something restricted to governments, spying, or secrecy. Surveillance and privacy are not necessarily in opposition and the latter can be a means of insuring the former as with access controls to information. While media attention to the problems associated with inappropriate surveillance (particularly by government) is present, there are also problems associated with the failure to use surveillance when it is appropriate. The emerging interdisciplinary field of surveillance studies analyzes these issues.

Surveillance Studies

The watchful and potentially wrathful (although also sometimes loving and protective) eye of the Biblical God of the Old Testament offers an early example of surveillance. More modern authors include Hobbes, Rousseau, Bentham, Marx, Nietzsche, Weber, and Taylor. Foucault (1977) (although writing about earlier centuries) is the grandfather of contemporary surveillance studies.

The field of surveillance studies came to increased public and academic attention after the events of 9/11 (Monaghan, 2006; Ball et al., 2012). But the topic in its modern form has been of interest to scholars at least since the 1950s. This is related to greater awareness of the human rights abuses of colonialism, fascism, and communism and anti-democratic behavior within democratic societies. The literary work of Huxley, Orwell, and Kafka and the appearance of computers and other new technologies with their profound implications for social behavior, organization, and society are also factors in the field's development.

In the form of *the surveillance essay* current writers from many disciplines and perspectives (e.g., political economy, social control, law and society, and criminology) draw on and extend the earlier theorists to describe the appearance of a new kind of society with new forms of social ordering (**Table 1**).

As ideal types, the terms in **Table 1** such as the 'panopticon,' 'disciplinary society,' or 'maximum security society' combine many strands that need to be separated if we are to move beyond sweeping claims made about surveillance. The concepts discussed in this article seek to bring greater precision and to add some leaves to the trees. One way to do that is to develop a middle range approach that fills out a general concept such as the *maximum security society* (as well as most of the other broad surveillance society naming concepts in **Table 1**) by identifying subsocieties that compose the surveillance society.

The maximum society concept draws parallels to the *total institution* and the maximum security prison and suggests that forms of control traditionally associated with the prison are diffusing into the broader society. But as an abstract notion, it does little to analyze variation in surveillance practices and changes over time. To do that the threads of the tapestry must be unwound in a series of subsocieties. Among components of the contemporary surveillance society are: a *hard engineered society*; a *soft and seductive engineered society*; a *dossier society*; an *actuarial society*; a *transparent society*; a *self-monitored society*; a *suspicious society*; a *networked society* of ambient and ubiquitous sensors in constant communication; a *safe and secure society* with attenuated tolerance for risk and with a strong emphasis on prevention; a '*who are you society?*' of protean identities, both asserted by and imposed upon individuals; and a '*where are you, where have you been, and who else is there?' society* of documented mobility, activity, and location. The broad approach of the surveillance essays is important in calling attention to contemporary changes, but such work generally does not take us beyond broad statements, does not adequately define surveillance, nor identify components that would systematically permit differentiating the new from the old forms, or making comparisons between various surveillance uses, contexts, and societies. In offering neither inclusive and nuanced definitions nor adequately elaborating dimensions, they fail to call attention to what is universal in human societies or to offer ways to analyze what is different.

Defining Surveillance

The English noun *surveillance* comes from the French verb *surveillir*. It is related to the Latin term *vigilare* with its hint that something vaguely sinister or threatening lurks beyond the watchtower and town walls. Still, the threat might be successfully warded off by the vigilant. This ancient meaning is reflected in the association many persons still make of surveillance with the activities of police and national security agencies. Yet in contemporary society the term has a far wider meaning.

What is surveillance? The dictionary, thesaurus, and popular usage suggest a set of related activities: look, observe, watch, supervise, control, gaze, stare, view, scrutinize, examine, checkout, scan, screen, inspect, survey, glean, scope, monitor, track, follow, spy, eavesdrop, test, or guard. While some of these are more inclusive than others and can be logically linked (e.g., moving from look to monitor), and while we might tease out subtle and distinctive meanings for each involving a particular sense, activity, or function, they all reflect what the philosopher Ludwig Wittgenstein calls a family of meanings within the broader concept.

At the most general level surveillance of humans (which is often, but need not be synonymous with human surveillance) can be defined as regard or attendance to others (whether a person, a group, or an aggregate as with a national census) or to factors presumed to be associated with these. A central feature is gathering some form of data connectable to individuals (whether as uniquely identified or as a member of a category).

A verb such as 'observe' is not included in the definition because the nature of the means (or the senses involved) suggests subtypes and issues for analysis and ought not to be foreclosed by a definition (e.g., how do visual, auditory, text, and other forms of surveillance compare with respect to factors such as intrusiveness or validity?). If such a verb is needed, to 'scrutinize,' 'regard,' or 'attend to' is preferable to observe, with its tilt toward the visual.

Many contemporary theorists offer a narrower definition tied to the goal of control (e.g., Dandeker, 1990; Lyon, 2001; Manning, 2008; Monahan, 2010). Taking a cue from Foucault's earlier writings, control as domination is emphasized (whether explicitly or implicitly) rather than as a more positive direction or neutral discipline. Yet, as Lianos (2003) observes, the modern role of surveillance as control must be placed in perspective alongside its fundamental importance in enhancing institutional efficiency and services.

Surveillance – particularly as it involves the state and organizations, but also in role relationships as in the family – commonly involves power differences and on balance favors the more powerful. Understanding this is furthered with comparisons to settings where control and domination are not central as with other goals such as surveillance for protection, entertainment, or contractual relations; where surveillance is reciprocal; and where it does not only, or necessarily, flow downward or serves to disadvantage the subject.

Authority and power relations are closely related to the ability to collect and use data. The conditions for accessing and using information are elements of a democratic society (Haggerty and Samatas, 2010). The greater the equality in subject–agent settings, the more likely it is that surveillance will be bilateral. Given the nature of social interaction and a resource-rich society with civil liberties, there is appreciable data collection from below as well as from above and also across settings. Reciprocal surveillance can also be seen in many hierarchal settings.Mann et al. (2003) refer to watchful vigilance from below as *sousveillance*.

The definition of surveillance as hierarchical watching over or social control is inadequate. The broader definition offered here is based on the generic activity of surveilling (the taking in of data). It does not build in the goal of control, nor specify directionality. In considering current forms we need to appreciate bidirectionality and horizontal as well as vertical directions. Control needs to be viewed as only one of many possible goals and/or outcomes of surveillance. When this is acknowledged, we are in a position to analyze variation and note factors that may cut across kinds of surveillance.

In his analysis of "The Look" Sartre (1993) captures a distinction between *nonstrategic* and *strategic surveillance*. He describes a situation in which an observer is listening from behind a closed door while peeking through a keyhole when "all of a sudden I hear footsteps in the hall." He becomes aware that he himself will now be observed. In both cases he is involved in acts of surveillance, but these are very different forms. In the latter case he simply responds and draws a conclusion from a state of awareness. In the former he has taken the initiative, actively and purposively using his senses.

Nonstrategic surveillance refers to the routine, autopilot, semiconscious, often even instinctual awareness in which our sense receptors are at the ready, constantly receiving inputs from whatever is in perceptual range. Smelling smoke or hearing a noise that might or might not be a car's backfire are examples. In contrast, strategic surveillance involves a conscious strategy to gather information. This may be in a cooperative or adversarial setting – contrast parents watching a toddler with corporations intercepting each other's telecommunications.

Within the strategic form, which to varying degrees ferrets out what is not freely offered, we can identify two mechanisms intended to create (or prohibit) conditions of visibility and legibility: material *tools* that enhance (or block) the senses and *rules* about the surveillance itself. While these are independent of each other, they show common linkages, as with rules requiring reporting when there are no available tools for discovery or rules about the conditions of use for tools that are available. A stellar example is the 'Lantern Laws' that prohibited slaves from being out at night unless they carried a lantern (Browne, 2015). Here, the emphasis is on requiring the subject to make him or herself visible given the limitations brought by darkness. But note also efforts to alter environments to make them more visible as with the creation of 'defensible space': via taking down shrubs or using glass walls (Newman, 1972) or less visible ala the architecture of bathrooms.

Within the strategic form we can distinguish traditional from the new surveillance. Examples of the new surveillance include computer matching and profiling, big data sets, video cameras, DNA analysis, GPS, electronic work monitoring, drug testing, and the monitoring made possible by social media and cell phones. The new surveillance tends to be more intensive, is extensive, extends the senses, is based on aggregates and big data, has lower visibility, involves involuntary (often categorical) compliance of which the subject may be unaware, tends to decrease cost, and reach remote locations. While the historical trend here is clear, it is more difficult to generalize about other characteristics such as whether or not surveillance has become more deceptive or more difficult to defeat than previously. Many forms are more omnipresent and often presumed to be omnipotent.

The new surveillance may be defined as scrutiny of individuals, groups, and contexts through the use of technical means to extract or create information. In this definition the use of 'technical means' to extract and create the information implies the ability to go beyond what is naturally offered to the senses and minds unsupported by technology, or what is voluntarily reported. Many of the examples extend the senses and cognitive abilities by using material artifacts, software, and automated processes, but the technical means for rooting out can also involve sophisticated forms of manipulation, seduction, coercion, deception, infiltrators, informers, and special observational skills.

Including 'extract and create' in the definition calls attention to the new surveillance's interest in overcoming the strategic or logistical borders that inhibit access to personal information. These inhibitors may involve willful hiding and deception on the part of subjects or limits of the natural world, senses, and cognitive powers. Create also suggests that data reflect the output of a measurement tool. The tool itself reflects a decision about what to focus on and the results are an artifact of the way they were constructed. Of course, constructions vary in their usefulness, validity, and reliability. Our perceptions of the empirical world are conditioned by where and how we look and these may vary in their fidelity to that world.

The use of 'contexts' along with 'individuals' recognizes that much modern surveillance attends to settings, or patterns of relationships and groups, beyond focusing on a given, previously identified individual. Meaning may reside in cross-classifying discrete sources of data (as with computer matching and profiling) that, when considered separately, are not revealing. Systems as well as persons are of interest. The collection of group data or the aggregation of individual into group data offers parameters against which inferences about individuals are drawn for purposes of classification, prediction, and response. Depending on the parameters, this may bring rationality and efficiency, but there is an inferential leap in going from *group* characteristics based on *past events* to *future* predictions about a given *individual*.

This definition of the new surveillance excludes the routine, nontechnological surveillance that is a part of everyday life, such as looking before crossing the street or seeking the source of a sudden noise or an unusual scent. It also excludes the routine attentiveness to, and interaction with, others that is fundamental to being a social being (as with mannerly behavior such as opening the door for another or offering a seat to an elderly person). An observer on a nude beach or police interrogating a cooperative suspect would also be excluded, because in these cases the information is volunteered and the unaided senses are sufficient.

Related but Distinct: Surveillance and Privacy, Privacy, and Publicity

How do surveillance and privacy relate? Surveillance is often wrongly seen to be the opposite of privacy. Kelvin (1973) emphasized this role of privacy as a nullification mechanism for surveillance. But at the most basic level, surveillance is simply a way of discovering and noting data that may be converted to information. Thus, depending on the context and role played, individuals or groups may be required, find it optional, or be prohibited from engaging in these activities, whether as subjects or agents of surveillance and communication. This obviously can involve invasions of privacy, as it was with the employee in a lab testing for AIDS who sold information on positive results to a mortuary.

Yet surveillance can also be the means of protecting privacy. Consider biometric identification and audit trails required to use some databases, or defensive measures such as a home security video camera. Privacy for whom, surveillance of whom, by whom, and for what reasons need to be specified.

Privacy like *surveillance* is a multidimensional concept whose contours are often ill-defined, contested, negotiated, and fluid, dependent on the context and culture. Among the major forms are *informational* (Westin, 1967), *aesthetic* (Rule et al., 1980), *decisional* (Decew, 1997), and *proprietary* (Allen, 2007) privacy. Informational privacy (Westin, 1967) is the most significant and contested contemporary form and involves the rules and conditions around personal information.

Breaches of decisional or proprietary privacy involve application or use of private information, rather than information discovery. While distinct, informational privacy shares with the other forms the key factor of control over access to the person or at least the person's data and the forms may be temporally connected. Thus, if individuals can control their personal information – whether not having to reveal their purchase of birth control pills (when this was illegal) or keeping paparazzi from taking pictures – they need not worry about that information being used.

Informational privacy encompasses *physical privacy*. The latter can refer to insulation resulting from natural conditions such as walls, darkness, distance, skin, clothes, and facial expression. These can block or limit outputs and inputs. Bodily privacy is one form of this, and its borders can be crossed by implanting something such as a chip or birth control device or removing something, such as tissue, fluid, or a bullet. Within informational privacy we find the conditions of anonymity and pseudo-anonymity, often referred to as being necessary for another type of privacy involving seclusion and being left alone. Personal information borders are obviously more difficult to cross if an individual cannot be reached via name or location.

Informational privacy can be considered as it ties to institutional setting (e.g., financial, educational, health, welfare, employment, criminal justice, national security, voting, and census); places and times; the kind of data involved, such as about religion or health; participant roles; and aspects of technology and media, such as audio or visual, wire or wireless, print, phone, computer, radio, or TV. Considerations of setting, location, time, data type, and means are central to legislation and regulation and rich in anomalies and cross-cultural differences.

A concept related to privacy is publicity. The two can be linked within the same framework. The common elements are rules about the protection and revelation of information. In some countries such as Canada the same officials are responsible for privacy and for freedom of information. In the first case there are rules giving individuals the right to control their personal information and in the second rules requiring that information not be restricted – that is, that it be made public. While sharing elements, for policy purposes there are major differences between the privacy of individuals and the secrecy of organizations. The standards for the latter should not automatically be applied to the former.

As nouns privacy and publicity can be seen as polar ends of a continuum involving rules about withholding and disclosing, and seeking or not seeking, information. Thus, depending on the context and role played, individuals or groups may be required, find it optional, or be prohibited from engaging in these activities, whether as subjects or agents of surveillance and communication.

When the rules specify that a surveillance agent is not to ask certain questions of (or about) a person and the subject has discretion about what to reveal, we can speak of *privacy norms*. When the rules specify that the subject must reveal the information or the agent must seek it, we can speak of *publicity norms* (or, better perhaps, disclosure norms). With publicity norms there is no right to personal privacy that tells the agent not to seek information, nor does that give the subject discretion regarding revelation. Rather, the reverse – the subject has an obligation to reveal and/or the agent to discover (Marx, 2011).

The moral expectations surrounding information as a normative phenomenon (whether for protection as with

privacy or revelation as with publicity and whether based on law, policy, or custom) can be differentiated from the empirical status of the information as known or unknown. To understand this distinction, we need the related terms, private and public – adjectives that can tell us about the status of information. Is information known or unknown, does it have an objective quality, can it be relatively easily measured? For example, in face-to-face encounters one generally knows the gender and face of a stranger, whether this is in the street, an office, or a home. The information is 'public' as in readily accessible, and this may be supported by anti-mask laws and requirements to wear symbolic items of clothing, tattoos, or badges. Absent such rules, the stranger's political or religious beliefs are more likely to be invisible and unknown.

Normative expectations of privacy and publicity do not always correspond to how the adjectives public and private are applied to empirical facts. Thus, the cell phone conversations of politicians and celebrities that have privacy protections may become public. Information subjected to publicity requirements such as government and corporate reports and disclosure statements may be withheld, destroyed, or falsified. Information not entitled to privacy protections, such as child or spouse abuse, may be unknown because of the inaccessibility of the home to broader visibility. The distinction calls for empirical analysis of the variation in the fit between the rules about information and what actually happens to it.

Privacy and publicity can be thought of in literal and metaphorical spatial terms involving invisibility–visibility and inaccessibility–accessibility. The privacy offered by a closed door or a wall and an encrypted e-mail message share information restriction, even as they differ in many other ways. Internet forums are not geographically localized, but in their accessibility can be usefully thought of as public places, not unlike the traditional public square where exchanges with others are possible or where others are visible as with open architecture. Erving Goffman (1971) in writing of 'relations in public' and 'public life' attends to the elements and possibilities within the immediacy of physical copresence. This is the strand of 'publicness' as visibility. It suggests the 'public' as known to at least one other person rather than to any rules about the status of information (that it must be revealed or concealed or to a legally defined place such as private golf course) as noted above. Thus, we can paradoxically speak of 'public order in private places' (Goffman, 1971: XIV).We can also speak about expectations of the private even within the public (Nissenbaum, 1998; Marx, 2001). In the latter case, since the information is available (such as with someone's appearance or a conversation overheard in a restaurant). But limits remain as with expectations about not staring or listening too closely to what others nearby are saying.

Structures and Processes

Regardless of whether we are dealing with traditional or the new surveillance, some common classificatory notions can be applied. In the case of surveillance social structures, for example, we can identify the *surveillance agent* (whether as watcher/observer/seeker/inspector/auditor/tester), while the person about whom information is sought or reported is the *surveillance subject*. The agent role can be further separated into the *sponsor*, *data collector*, and *initial* or *secondary user*.

Many contemporary concerns over surveillance involve the practices of large organizations relative to employees, clients, or the public. *Organizational surveillance* is distinct from the *nonorganizational surveillance* carried about by individuals. At the organizational level, formal surveillance involves a constituency. Organizations have varying degrees of internal and external surveillance (Rule, 1973). Erving Goffman (1961) has identified many kinds of employee or inmate monitoring, such as within 'total institutions.'

Within an organization *internal constituency surveillance* (scrutiny of insiders as with work monitoring) contrasts with *external constituency surveillance* (attending to outsiders such as customers, patients, and travelers). *External nonconstituency surveillance* involves organizations monitoring their broader environment in watching other organizations and social trends. The rapidly growing, understudied field of business intelligence fits here.

In *nonorganizational surveillance* the watching is apart from a formal organizational role. It may involve *role relationship surveillance* as with family members (parents and children, the suspicious spouse) or friends looking out for and at each other (e.g., monitoring location through a cell phone). Or it can involve *non-role relationship surveillance* – as with the free-floating activities of the voyeur whose watching is unconnected to a legitimate role.

Agent-initiated surveillance illustrated by compliance checks such as an inspection of a truck or a boat is distinct from *subject-initiated surveillance* – as with volunteering to participate in consumer reward programs. The agent and subject of surveillance can merge with *self-surveillance* – where individuals watch themselves (home alcohol or reproductive tests).

While distinct, subject and agent can be intertwined, as with parallel or *co-surveillance* (e.g., remote health monitoring in which both the monitored person and a health agency simultaneously receive signals about the subject). In the latter case co-surveillance is *nonreciprocal* with personal data from the watched going to the watcher. This tends to be the case with employers, merchants, doctors, teachers, and parents and reflects power and resources differences. In contrast, *reciprocal surveillance* is by definition bidirectional, as with social networking sites. But reciprocal, need not mean equal. Surveillance that is reciprocal may be *asymmetrical* or *symmetrical*. In a democratic society citizens and government engage in reciprocal but distinct, and shifting forms and degrees of mutual surveillance. These questions draw attention to who is entitled to and/or able to play the agent role and who is the subject? New tools may bring increased democratization (or a better term – equalization) as with readily available cell phone cameras and Internet access or the tools may be restricted as with access to satellites, private databases, and sophisticated data mining.

A measure of democracy is the extent of restrictions on and mandatory requirements for information flows across actors and sectors. For example, what is the ratio over time of what governments and large organizations are expected to (or may) reveal about themselves (e.g., freedom of information, truth in advertising laws and policies, and conflict of interest statements) and what citizens are expected to reveal about

themselves to governments and large organizations. Contrast the extremes of a *totalitarian government* that has no obligation to reveal anything to citizens (who must reveal all to government), with the unrealistic case of a *fully open government* that must reveal all to citizens (who in turn reveal only what they choose to government).

The concepts above emphasize structure (i.e., patterned forms of behavior and organization). Structure implies that the topic is static and fixed at one point in time, yet surveillance also needs to be viewed as a fluid, ongoing process involving interaction, strategic calculations, and negotiations over time. Among major processes are the *softening of surveillance* (in which minimal invasiveness, manipulation, persuasion, and low visibility replace traditional coercion); efforts to create the *myth of surveillance* (generating fears supportive of the need for increased surveillance and/or claims that the solution is more effective than it is); the *monetarization* of personal data so it can be sold to marketers, governments, and individuals for purposes of sorting and the *commodification* of surveillance in which it (or protection from it) become products to be purchased; *surveillance slack* – the relative gap between potentials and practices; and various techniques of neutralization. The latter are strategic moves by which subjects of surveillance seek to subvert the collection of personal information such as direct refusal, discovery, avoidance, switching, distorting, counter-surveillance, cooperation, blocking, and *masking*. Equivalent counter-neutralization moves by agents are also present (Marx, 2003).

Another way to think about process is to consider the links between the distinct activities covered by the umbrella term surveillance. The most common meaning refers to acts of data collection, but these occur within a broader system of connected activities. Seven kinds of activity conceived as *surveillance strips* can be noted: *tool selection*, *subject selection*, *collection*, *processing/analysis*, *interpretation*, *uses/action*, and *data fate*. Considered together these strips constitute the *surveillance occasion* and offer a way to bind a given application.

Viewing surveillance in stages also permits us to see one link between *surveillance* and *communication* – the two related topics that are rarely connected. However, at the use stage suggested above surveillance results can be used for targeted marketing, solicitation, and propaganda (Gandy, 1993). Both can involve the crossing of personal borders and respect for, or the disavowal of, a person's dignity – in one case to take from and in another to impose upon, the person in contexts of roles, rules, and expectations. They also share some issues of interpretation and meaning regarding the data surveillance collects and the content of a message.

The 'career' of a particular surveillance tool may also be tracked as it emerges and then may diffuse – whether in a jagged or in a more linear direction. In the case of the latter this may be through *surveillance creep* or *gallop*, often displacing other means along the way and bringing new goals and users. There may also be *surveillance constriction* as a new, unregulated tactic becomes subject to limitations and even prohibitions. Thus, the rampant surveillance that computerization and related forms of electronic monitoring and communication made possible has been somewhat curtailed by laws and policies. An early example was the Electronic Privacy Protection Act of 1986 or with the new concerns that DNA brought the 2008 Genetic Information Nondiscrimination Act. Robert Smith (2013) reports on the vast expansion of state and federal laws regarding surveillance and privacy.

Understanding Surveillance and Value Conflicts

There are many ways of approaching surveillance from the social sciences, and the perspective and methods chosen need to reflect specific questions and local situations (e.g., How were suspects identified before photography was invented?, What are the most important causes of the emergence of a surveillance society?, and Do young people differ in their assessment of the privacy implications of social media from older people?) However, regardless of the kind of question, our understanding will benefit from awareness of factors such as the level of analysis and conflicts in values discussed next.

Understanding surveillance will be furthered to the extent that we:

1. Identify questions and levels of analysis. Central here for both explanation and policy purposes is awareness of social and cultural factors present within different contexts and institutional settings. In addition, how we account for and judge surveillance should depend on the role played and the characteristics of the tool, goals, the kind of data involved, and the values at stake.
2. Identify variation and then look for correlations and explanatory causes/drivers within a framework of soft determinism, but do not confuse correlation with causality.
3. Realize that the same causal factor(s) can have different outcomes and the equivalent outcomes can have different causes.
4. Appreciate the advantages of a loose systems approach with some open-ended borders and room for (but limits upon) exogenous inputs.
5. Attend to beginnings (or at least prior circumstances) – everything was preceded by something before and new ways of meeting human needs must be compared with old ways.
6. Note that while some things change, others remain the same.
7. View surveillance as a process, as well as a structure or a tool. Central to that is studying interactions involving agents, subjects, third parties, and audiences over varying time periods.
8. Ask about the appropriateness of both means and ends. Desirable ends do not justify doubtful means, and good means can be misused. Good goals and purity of motives are not sufficient justification. Consider the acceptability of means and ends independently, as well as in their relationship to each other. Recognize that a given tool can serve a variety of goals and that a given goal can be met by a variety of tools.
9. Differentiate facts from values. No matter how sound the method or clear the findings, a leap to values, ethics, and political choices always remains in what we come to see as facts and in the ends for which surveillance is used.
10. With respect to values (and the goals and specific applications to which they are related) be aware of how their

abstract nature and conflicts between them mean that surveillance will often be subject to legitimate disagreements among well-meaning persons. (The issue of value conflicts is vital and I discuss it in the following paragraphs.)

Value conflicts are everywhere, like the weather. Thus, we seek privacy and often in the form of anonymity, but we also know that secrecy can hide dastardly deeds and that visibility can bring accountability. On the other hand, too much visibility may inhibit experimentation, creativity, and risk taking. And while we value disclosure and 'permanent records' in the name of fairness and just deserts, we also believe in redemption. New beginnings after individuals have been sanctioned, or after they have otherwise overcome limitations or disadvantages, are fundamental to the American reverie.

In our democratic, media-saturated, impression-management societies, many of us want to both see and be seen (e.g., social media) even as we also want to look the other way and be left alone. We may want to know but also be shielded from knowing.

We value freedom of expression and a free press but do not wish to see individuals defamed, harassed, or unduly humiliated (whether by the actions of others or their own). Also as ideals, we desire honesty in communication and also civility and diplomacy. In interpersonal relations (in contrast to the abrasive talk shows) we may work hard to avoid embarrassing others by not seeking certain information or by holding back on what we know. We value the right to know, but also the right to control personal information. The absence of surveillance may bring freedom from censorship, but also open the door to the worst demagogues, liars, and self-deluded snoops. Yet undue surveillance chills nonconforming communication and is the companion of repression.

Individuals expect organizations to treat them in a fair, accurate, and efficient manner, and to judge them as unique, not as undifferentiated members of a general category, while at the same time, they hesitate to reveal personal information and desire to have their privacy and confidentiality protected. Meeting the first set of goals necessarily requires giving up personal data, and up to some point, the more one gives up, the more accurate and distinctly reflective it will be of the unique person. Yet, the more data one reveals, the greater the risk of manipulation, misuse, and privacy violation. At the same time, knowing more can bring new questions and less certainty to surveillance agents. Depending on their role and social location, individuals and groups differ in the relative importance they give to privacy as compared to accuracy.

The individual's expectation to be assayed in his or her full uniqueness may conflict with an organization's preference for responding to persons as part of broad common aggregates – something seen as more rational, effective, and even efficient. The idea of due process and fairness to be determined in each individual case can radically conflict with an organization's utilitarian goals and bottom line. In the criminal justice context, for example, civil liberties sometimes conflict with the goal of effective enforcement. The case for *categorical surveillance* (without cause) versus *particularized surveillance* (only with cause) and for prevention versus after-the-violation responses can be well argued either way.

Culture sends contradictory messages. On the one hand, individuals are expected to submit to surveillance as members of a community that supports the common good and fairness (e.g., the required census or social security number that apply to all) or that allows one to participate in certain behaviors such as traveling, buying on credit, or obtaining an entitlement. Yet fairness apart, when such surveillance goes beyond minimal verification and is done in a coercive manner, it may conflict with the expectation that before personal information borders are crossed, there needs to be some grounds for suspicion. If agents have to wait to do surveillance until they have cause in situations where there is evidence of preparatory actions or where violations are of low visibility or hidden outright, many violators get a free ride. This limitation protects the innocent against unnecessary searches. Yet, it can also mean failing to prevent terrible events – for example, in the case of 9/11, where well-intentioned policies from another era as well as many informal factors blocked the FBI and CIA from exchanging information about the perpetrators.

If your tools work and if you search them all, you will likely get the guilty, not to mention the innocent and this is likely inefficient. Profiling as a surveillance tool permeates society far beyond ethnicity, religion, or national origin. In contemporary society, with its emphasis on prevention, the push is toward broader and deeper searching for the absent cause. The dilemma can be identified but not solved because observers differ in judging the trade-offs between equality, fairness, grounds for suspicion, invasiveness, prevention and effectiveness and the likelihood and seriousness of risks, and the potential for identifying and remedying failures.

The existence of practices with a good potential for abuse traditionally leads to demands for regulation. Thus, we see bureaucratic and legalistic responses. These may lessen problems, but ironically, can also lead to expanded use of potentially troubling means. In contrast, without a formal mandate legitimating and acknowledging the tactic, agents may hesitate to use it because of uncertainty about where to draw the lines.

The above discussion involves conflicts between abstract values. But more concrete conflicts may also appear in applying the tools. The intrinsic properties of a device may work against the agent's desire for secrecy. While much contemporary surveillance is defined by its ability to root out the unseen and unknown, it also paradoxically may reveal itself through electrical, chemical, and other forms of data. That which silently gathers the emanations of others, if not exactly a mirror image, nonetheless emanates itself, offering discovery possibilities and means of neutralization to technically competent adversaries. The watchers may also be watched by the means they apply to others. Also, if an agency publicizes a surveillance system that has as one goal, making citizens feel more secure, it may in addition have the opposite effect because it sends the message that dangers are so great as to warrant the need for such a system. Or this same publicity may alert committed malefactors to the presence of surveillance, triggering evasive, blocking, or displacement means – a kind of unfair (at least to the law-abiding public) warning. Thus, advertising the means versus keeping them secret highlights the potential conflict of goals between deterrence and apprehension so apparent with undercover work. The existence of practices with a good potential for abuse traditionally leads to demands

for regulation. A bureaucratic and legalistic response may lessen problems, but ironically, it can also lead to expanded use of potentially troubling means. In contrast, without a formal mandate legitimating and acknowledging the tactic, agents may hesitate to use it because of uncertainty about where to draw the lines.

A final mandate: with respect to the significant very complex issues new and old forms of surveillance bring to a democratic society, neither a pessimist nor an optimist be. Unless, of course, your view is based on empirical evidence, and a logical and well developed argument that defines its terms and identifies its background assumptions regarding both values and the empirical workings of the world.

Surveillance practices need to be understood within specific settings in light of history, culture, social structure and the give and take of interaction, and require the appreciation (if not necessarily the welcoming) of the ironies, unintended consequences, and value conflicts that limit the best laid plans. Mushrooms do well in the dark, but so does injustice. Sunlight may bring needed accountability through visibility, but it can also blind and burn.

There is a path, however twisting, changing, and bramble and illusion filled between Tennyson's early nineteenth century optimism, "For I dipt into the future, far as the eye could see, saw the world, and all the wonders that would be (Ricks, 1989) and Einstein's 20th century worry that technological progress can become like an axe in the hand of a criminal" (Folsing, 1998). Yet, hope must trump dread as we keep the faith with respect to both the importance of having a dream and the ameliorative potential of critical analysis. Empirical and scientific knowledge about human and social conditions can result in the improvement of those conditions, or maybe stop them from getting worse.

The study of surveillance is a reminder that while they (whether the state, commercial interests or new, expanding public–private hybrid forms) are watching us, we as citizens must watch them. And as baseball player Yogi Berra said, "you can see a lot by looking." Making surveillance (as with any technology) more visible and understandable hardly guarantees a just and accountable society, but it is surely a necessary condition for one.

Abstract

This article presents a general introduction to the subject of archaeological field methods, and therefore does not deal with many distinct areas or challenges to the discipline. Archaeology is a dynamic, inherently interdisciplinary field of study in that new research techniques continue to revolutionize its modes of thought and methods, and researchers are asking different questions of the data today from those they asked only a few years ago. On both scientific and theoretical fronts, therefore, the field is developing at a fast pace. In the past few years, archaeology has become a global discipline with many researchers applying the same systems such as geographic information systems along with aerial reconnaissance and remote sensing. We begin with 'archaeology' as a term, and cover a brief history of the discipline, its importance, types of archaeological sites, fields of archaeological study, and dating systems used in the discipline. The focus then changes to survey, excavation and ethical considerations, excavation and the modern developments in the discipline.

The Term 'Archaeology'

The term 'archaeology' comes from the Greek word, *arkhaiologia*, meaning the 'discussion or discourse about ancient things' (*see* Archaeology, Theory in). By definition, archaeology is the science by which the remains of the ancients can be methodically and systematically studied to obtain a picture as complete as possible of ancient culture and society, and thereby to reconstruct past ways of life (Gamble, 2008). An antiquarian doctor of Lyon, Jacques Spoon, first used the term 'archaeology' in the seventeenth century. Archaeology is a discipline that involves the scientific method of study, observation, recording, and experiment (Moshenska, 2013). Archaeologists study in detail the complete life of cultures and their patterns of change in an attempt to delineate the causes and effects of the cultural process. The fascination of archaeology lies in the solving of long-standing problems and in the discovery of the meaning of things. The excitement of archaeology lies in the new problems which recent findings produce.

The History of Archaeology

The earliest 'archaeologist' was the sixth-century BCE King Nabonidus of Babylon who excavated a temple down to its foundations, which had been laid thousands of years before (Crowell, 2007). Even the Roman emperor Augustus was a collector of 'giant' bones and ancient weaponry. With time, Europeans began to collect burial urns, chipped flint stone, and ground stone tools which some believed were amulets. In 1719, the Austrian Prince d'Elboef led the first excavation to Herculaneum, which had been destroyed along with Pompeii in AD 79 when Mount Vesuvius erupted. Thereafter, when pieces of classical sculpture began to turn up, artists began to study their shapes and decoration and collectors began to collect, proudly display, and discuss their forms. With time, more people began to describe what they recognized as ancient monuments and excavations were undertaken to retrieve more and more objects. In the mid-eighteenth and early nineteenth centuries, digging for ancient objects became the pursuit of gentlemen of the leisured class and professionals: they became known as antiquarians and formed clubs to discuss the merits of ancient artifacts.

Archaeology as a pursuit using scientific systems of recovery began in the nineteenth century, along with the growing realization that humankind had an ancient past that could be investigated in a methodical way. The names of most important archaeologists from the early days include Sir William Matthew Flinders Petrie in Egypt, Robert Koldewey in Babylon, the duplicitous Heinrich Schliemann in the Aegean at Troy, Mycenae and Tiryns, and General Augustus Pitt-Rivers in Britain. Later pioneers were Sir R.E. Mortimer Wheeler in Britain and India, George Andrew Reisner and Sir Leonard Woolley in the Near East, Max Uhle and Alfred Vincent Kidder in America, and François Bordes and André Parrot in France.

In the present day, archaeology has grown into a multidisciplinary, methodical, problem-oriented search for the past (Insoll, 2007). It now involves above-ground research as well as excavation and a host of specialists is required, depending on the site. Background research as well as excavation has become meticulous. The study of pottery, for example, involves not only typologies but sophisticated scientific testing by neutron activation analysis to understand the chemical components and to identify the sources and cultural patterns as well as to assess trade relationships.

Archaeological questions extend far beyond the excavation and interpretation of any single cultural group, geographic region, or chronological period of time. In theory, all archaeological study is aimed toward an explanation that will provide a conceptual basis for the reconstruction of the past, and the where, how, and why of the changes that took place.

The Importance of Archaeology

Archaeology is unique in that it encompasses the whole world over the past 2.5 million years in order to reconstruct the past. It includes the research of all kinds of sites – underwater wrecks or port installations, caves, jungles, deserts, and mountain-top

sites; wherever past activity has taken place. Archaeology wants to discover where and when humankind developed and began to practice art, agriculture, and technology and became urbanized. It is our route to our understanding of ourselves, for in order to know where we are going we have to reconstruct and understand the past and where we have come from.

Archaeology continues to give us a broad and long-term view about the past and the events that conditioned us. There is an implosion of new answers to research on how, where, and when humankind began; our development of technology and the arts; the expression of our ideas in writing; and how we harnessed the environment brought about by the domestication of plants and animals, and developed agricultural systems (Bahn and Renfrew, 2005). Archaeology helps us to understand the processes of becoming urbanized, how we developed complex societies, and to understand our basic needs.

Archaeological Sites

Archaeology covers a wide diversity in time, space, subject matter, and approach. An archaeological site can be any place that has been a scene of past human activity, including a briefly settled campsite, a shipwreck, a monumental city, or the evidence of any number of different combinations of human remains. Any place where human beings have established themselves, even momentarily, is considered a site.

As each archaeological site is a unique time capsule, each has its own distinct character and problems. Types of sites are often labeled by their prehistoric or historic context, their function, their general topographic nature, or according to whether they are composed of one or many levels of occupation. Sites represent a body of data relevant to their setting and their cultural patterning and must be interpreted both in relation to this local setting and as a link between cultures. Sites may be small or large. Small sites are far more numerous throughout the world and may range from hunting or fishing stations to small village communities. There are prehistoric plains or riverside terraces such as Olduvai Gorge in Tanzania, Africa (Blumenschine, 1969–present); there are caves such as Chou Kou Tien near Peking, China where the Peking Man was found; or those containing Upper Paleolithic art, like Lascaux in France (Wallis, 2013).

Large sites are generally cities, temples, large tells – artificially built-up mounds in the Middle East with one city built on top of the other (known as *höyük* in Turkish or *tepe* in Persian). The ancient mound of Jericho, Israel is particularly important, revealing evidence dating back to 8000 BCE (Lalleman, 2008). A more recent tell of the Mississippi Basin was built by the Mound Builders of North America in about 1300 CE (*see* North America, Archaeology of). There are monumental cities such as classical Rome, Mesoamerican Tikal in Guatemala (*see* Mesoamerica, Archaeology of), or Angkor Vat in Cambodia (*see* Southeast Asia, Archaeology of). There are sacred areas reserved for ritualistic functions such as Stonehenge in England or the statues of Easter Island. There are cemeteries and tombs such as those of Mycenae in Greece; the Pyramids in Egypt; or the mounds of Ohio, Illinois, or Mississippi. Famous sites also include underwater shipwrecks and harbors discovered worldwide off the shores of the Mediterranean, or near Oslo, Norway, where early Viking ships have been recovered.

The selection of a site for excavation therefore depends upon what the excavator (principal investigator) wants to find, and what problems will be answered by excavation. What is the nature of the evidence? It usually involves a problem to be solved – How has the site been built up over time? What is its environment and how has this changed? Using a research design, a review process is undertaken which includes the preliminary analysis of the site, the evaluation of the probable results, the examination of the costs, and the evaluation of organizational abilities and needs to carry out the tasks involved.

Archaeological Studies

Many types of archaeology have evolved over the years. There are Old World (Eastern Hemisphere) and New World (Western Hemisphere) prehistoric specialties, based on the stone tools humankind produced. The Paleolithic, Mesolithic, Neolithic, Bronze Age, and Iron Age are specialties (Toth and Schick, 2009). These are broad artificial classifications with subdivisions. As far as the discipline in which it has received attention, Old World archaeology is a separate subject in some schools, or is associated with departments of classics or near-Eastern studies, history, or art history. In the New World, prehistoric specialists may concentrate on the Paleo-Indian, Archaic, and Woodland periods (Kelley, 2003). Then both Old and New World archaeology move into historical archaeology. In the Old World there are experts who are devoted to Classical archaeology (the worlds of Greece and Rome) or Biblical archaeology (the areas encompassed by the Holy Land) (Cline, 2009).

Similarly, many kinds of specialties have developed in archaeology, for example, industrial archaeology; the study of manufacturing and salvage archaeology; the rescue work done before a modern construction takes place such as land development, or urban renewal, or when a pipeline, road, or dam is built. There are also technical specialties of people who concentrate on specific techniques such as ceramics, lithics, paleobotany, palynologists (specialists in pollen), and dendrochronologists (specialists of tree ring growth) among many others, including computer specialists who lend support to all these areas.

Since the 1960s in America, archaeology as a subdiscipline also has been associated with anthropology (Hicks, 2013). As anthropology is the study of humanity, anthropologists generally observe the behavior of present-day people in order to explain and reconstruct their behavior patterns. In so doing, they have to make assumptions about past behavioral patterns as set against the environment of the present.

Anthropology is divided into several subfields among which are social and/or cultural anthropology; physical or biological anthropology; linguistic anthropology, which includes the interpretation of oral history; demographic anthropology; ethnic anthropology; cognitive and symbolic anthropology; enthno-archaeology; and archaeoastronomy (the study of ancient astronomical events) (Harrison-Buck, 2014).

Dating Systems in Archaeology

The term 'culture' is used when assuming that a group of people exhibits shared behavior. Archaeologists want to be able to establish accurate space and time frameworks or dates for the cultures they are researching. In short, archaeologists want to establish the site context, culture, and chronology. Laboratory methods provide what are known as absolute dating methods, and relative dates are ascribed to archaeological strata based on the site deposition or stratigraphy and the discovery of cultural artifacts similar to those found at other sites (*see* Chronology, Stratigraphy, and Dating Methods in Archaeology).

Absolute dating is a date given in specific years, in terms of chronometrical dating or the calendar. A date given as BP is a date before 1950. BC means 'before Christ' (although nowadays BCE is often used, meaning 'before the Common Era'). CE (Common Era) is used instead of the old term AD, meaning *Anno Domini*, or after the birth of Christ. Absolute dates can be established by laboratory analyses like radiocarbon dates (C-14) (Boaretto and Poduska, 2013), potassium–argon, thermoluminescence, archaeomagnetism, and palaeomagnetism, among others. These are geochronologic methods used for determining the absolute date of a deposit.

Relative dates are based on the stratigraphic deposition – the principles of superposition, association, and correlation (Gamble, 2008). Superposition assumes that the uppermost stratum (soil level) was deposited last and the lowest stratum was deposited first; thus the reasoning assumes that lower strata are generally older than the layers above them. Association assumes that the artifacts found in the same closed and sealed archaeological context are contemporary and are therefore presumed to be culturally and temporally associated. Correlation assumes that, once cultural associations have been determined, artifacts can be cross-culturally correlated with artifacts from other site cultures and they can be expected to have been manufactured at the same time, and therefore to possess the same relative date.

Archaeologists use seriation as a method of relative dating (Porčić, 2013). Seriation involves the ordering of specific artifact types from an earlier to a later time sequence by the use of a typology. In creating a type series, the archaeologist assumes that artifacts have formal attributes that can be measured like raw material, length, width, thickness, color, weight, and so on, and that these nonrandom attribute factors were used as a standard by the maker. Therefore, a typology is comprised of types which are a cluster of attributes in a class of objects and these can be given relative dates that can be used to date the stratification.

Once associations have been defined cultural levels can be inferred. A cultural level represents the choices of a particular social group, such as the classical Greeks. The data collected in such a cultural level depict a known and recognizable set of ideas that are then represented as the cultural products of that society.

Archaeological Survey

Survey includes exhaustive historical research, map reading, geomorphologic and geographic analysis, aerial photography, geospatial survey like Light Detection and Ranging (LiDAR), and ground-level surveys including geophysical surveying techniques (Johnson and Millett, 2013). Historical research includes all previous modern and historic research of an area to be surveyed – excavation reports, artifact studies, and the conclusions drawn by previous researchers. In-depth bibliographic research provides essential background information.

All archaeologists are concerned with surveying as a means of planning and laying out the area to be studied or excavated. Surveying is generally the first step in all archaeological projects, and is often the last step before the completion of the excavation. Using maps, aerial photos, airborne LiDAR, satellite imagery, and whatever background information is available, ground-level surveys can be undertaken on foot to understand the physical features of the site as well as the artifacts – in short, all the material cultural remains of the site or the culture (Johnson and Millett, 2013). The site is then located according to Global Positioning Systems on a map or within a geographic information system (GIS), and its location is established and officially reported.

As a branch of engineering, surveying is the science that accurately determines the shape, area (size), and positions of a site's surface by the measurement of certain points. It includes the measurements of horizontal distances and elevations, and determines the direction and relationships of angles by the use of optical instruments. There are several principal classes of survey: *geodetic* surveys, *photogrammetric* (picture-measured) aerial surveys, and *plane* surveys. Geodetic surveys are used for the study of large areas like countries or continents, and take into account the curvature of the earth's surface. Satellite photographs have become important to the archaeological analyses of large landforms. Photogrammetric surveys are the science of taking detailed vertical or oblique photographs from an aircraft for the reliable measurement of the earth's features. Plane surveying is used for small areas of archaeological focus in which the curvature of the earth's surface is not measured. In the past few years, archaeologists have begun to conduct digital surveys using plane-mounted LiDAR units that generate an accurate three-dimensional model of the ground surface, archaeological features, bodies of water, and vegetation (Chase et al., 2012; *see* Geospatial Applications in Archaeology). Preliminary survey also consists of a systematic walking over the site recording standing structures and features as well as artifacts and material scatters. Depending upon what type of survey is to be conducted, artifact concentrations may be collected, processed, and studied to indicate the type of site and its artifact range. The survey should establish the site size, what kind of site it may be, its time span, and, if possible, its depth of deposit.

Depending on the site, three principal types of survey are usually conducted before excavation: (1) the land survey for the proper planning and laying out of the site which includes the site grid; (2) the topographic survey which is the measurement of elevations representing the surface of the area; and (3) the ongoing excavation survey, which is made during excavation to control the location of archaeological structures, features, and objects and providing these with elevations (Dupras et al., 2011). Anomalies and physical features are then thoroughly mapped and described as well as factors like vegetation and soils.

Decisions then may be taken as to what additional surveying equipment will be used to look at the subsurface features. Geophysical surveying techniques employ devices that either transmit an electromagnetic wave into sediments and record

the round-trip travel time of these waves or passively receive ambient electromagnetic waves (Oswin, 2009). Such devices include ground-penetrating radar, electrical resistivity meters, and magnetometers. These devices and others can identify subsurface anomalies that can either be mapped using only geophysical devices or tested through excavation. Only when the comprehensive survey has been completed can the researcher decide if excavation is justified, and if it is, where it is to begin and what course it is to take.

Excavation and Ethical Considerations

Even before a site is excavated, preservation, and consolidation measures must be seriously considered and implemented. How will the site be left after the excavation is completed? As excavation is destruction, one of the most important considerations is the site's stratigraphy, its depth of deposit, and its characteristics. We need to conserve and protect the excavated sites and monuments from all periods and in all parts of the world. Furthermore, we need to protect sites against the threats from human intervention, mass tourism, and building development, as well as from the elements of natural deterioration and neglect. Looting is an age-old problem. There are those who clandestinely excavate to sell artifacts at an enormous profit. Although artifact-rich countries have the legislation to prevent the illegal excavation and export of their country's patrimony, they lack consistent regulatory measures to police looters, dealers, and the exporters of their antiquities. If we are to preserve our common human heritage, the protection of cultural patrimony has to become everyone's priority.

There have been changes in the ethical standards observed by archaeologists today. Ethical standards in archaeology may be defined as the obligations of a professional or an amateur to the excavation; to the country, state, or area in which it is located; to the public at large; and to fellow archaeologists (Scarre and Scarre, 2006). Today's archaeologists strive to work and live according to a high standard of behavior, applying their knowledge to enhance the reputation and achievements of archaeology as a whole and for the benefit of human knowledge. Many archaeological associations have drawn up ethical codes that have been accepted by international archaeological societies: the codes of the Archaeological Institute of America, the Register of Professional Archaeologists, and the Society for American Archaeology.

Who will be responsible for the care and upkeep of the site over time? And what should be done to care for site artifact collections? Where are they going to be stored, who is going to study them, and on what time schedule? What is to be their final disposal – a museum, reburial, and, if the latter, where will they be buried? Today the archaeologist has the responsibility of addressing such issues and these should be best addressed before excavation takes place (*see* Archaeology, Politics of).

Excavation

Excavation is the deliberate recovery of buried objects in relation to the layer or stratum and other associated objects in its original deposit. The principle of excavation is that artifacts, nonartifactual materials, and architectural features are not randomly distributed, but are deposited by people. Their position in the earth reflects the cultural, economic, and social behavior of humankind that can be studied by means of excavation. This is the basis for the functional reconstruction of the site. It is only through excavation that the archaeologist can collect and extract a wide range of physical information or obtain a sense of the people who lived, worked, and perhaps worshipped at a site. The archaeologist does this by describing the evidence the people left behind – the architectural features and objects. It is only through excavation that we can align these physical features in time and space so that the functional reconstruction of the processes involved can be determined. In this way we can better understand and interpret the causes, changes, and processes that the ancients used to bring about change.

Excavation is the method of removing objects and uncovering stationary features that have been concealed by later deposits (Sharer and Ashmore, 2003). It involves the removal of layers or strata in reverse order to the way in which they were laid down, gradually revealing each successive stage in the history of the people who used the site. Because excavation is the means by which information is unearthed, it must be conducted methodically so that whatever is found can be seen and studied within its own context. The main objectives of excavation are to uncover the position of objects as well as floral and faunal data, and to plot their location on a horizontal plan (Sharer and Ashmore, 2003). It also involves the meticulous recording and sequencing of successive layers on the vertical section by position and depth measurements. Finally, the goal is to relate such data to the total environment of the site and to assess its relationship to other sites in the area.

Modern Developments in Archaeology

Major developments in archaeology took place in the late 1990s with the advent of computer technology: remote sensing using images from airplanes, satellites, and drones; web pages; virtual reality; computer simulations; digital recording devices like cameras and tripod-mounted LiDAR; digital record keeping systems like relational databases; geospatial analytic softwares like GIS (Hritz, 2014); and the greater use of the hard sciences including DNA analysis (Grosman et al., 2014).

In the 1960s, American archaeologists began to challenge the traditional archaeological academy and argued that the discipline had become simplistic. As a result of this critique the 'new archaeology' was developed, emphasizing the importance of the processes within the society being studied. This was known as 'processual archaeology,' and it emphasized the value of objective, logical explanation, and the descriptive processes that can produce testable assumptions. They believed that culture should be studied as sets of systems and subsystems as they relate to the environment, the economy, and patterns of subsistence. They also emphasized that the interrelationships between different sectors of the society should be explainable so that specific developments could be established throughout time (Harrison-Buck, 2014).

They failed to stimulate the traditionalist majority who practiced archaeology as they had before and who believed that there were no universal laws governing human behavior.

The merit to the then-new approach to archaeological data opened the way to a vast array of new theories including Marxist, neo-Marxist positivist, structuralist, poststructuralist, postprocessualist, deconstructionist, and probabilist views along with other theoretical constructs (McGee and Warms, 2011). The postprocessual school of archaeologists adheres to aninterpretative archaeology, which insists on emphasizing history, philosophy, and, whenever possible, literary studies. Interpretative archaeologists place importance on the fundamental uniqueness and diversity of culture, believing there is no one governing law that can apply either to archaeological research or to the interpretation of the past. These theories hold some truth, provide stimulating hypotheses for our explanation of the past, and are used by many who thoughtfully interpret the probabilities of the evidence. Now archaeologists are wrestling with the ideas of multivariate explanations – and many continue to build idealized models for their interpretations.

Conclusion

By and large, archaeologists are dedicated researchers and teachers. As for future directions in theory and research, evaluation can be said to drive archaeological standards. By clearly specifying the outcomes in measured ways, archaeologists will change the way they excavate and publish. In the training of students, field directors hope they will train people who possess the qualities and attributes desired in a competent archaeologist. As an archaeological project is expected to foster a shared sense of a shared mission between the field researcher and the principal investigator, both will strive to reach a common goal. Archaeology is best taught through active learning processes, and principal investigators help students by gauging their progress and identifying and overcoming barriers to the excavation as a whole. The developmental process of archaeology is most effective when the goals are known so that the whole team can work together toward the shared goals, collaboratively devising strategies to overcome any obstacles. Our understanding of the past is in a constant state of change due to new discoveries and advances in our knowledge. It will never be finished.

Today archaeology has developed into a complex discipline with a vast literature and a range of specialties that are well beyond the competence of a single researcher. More and more data are being produced, museums are overwhelmed with objects, and, even with the advent with the computer, many artifacts have remained unanalyzed or unregistered. There is a crisis in the discipline due to the fact so much data have been produced, and as excavation involves the destruction of the site, archaeologists must be aware that the discipline may self-destruct unless it puts its house in order. It faces considerable challenges and risks ahead and it must develop an international dialogue among its leadership that is committed to a strategy which will ensure the saving of the past for the future.

This article is a revision of the previous edition article by P.P. Mohler, volume 22, pp. 15311–15314, © 2001, Elsevier Ltd.

Abstract

Social scientists seek answers by way of research methods. One such method is survey research, which involves the collection and analysis of data obtained from individuals, usually through questionnaires. A specific 'know-how' and infrastructure is needed to conduct surveys and obtain reliable and valid data. Survey research centers and companies provide such expertise and the services. The following entry presents some of the most important survey research centers and companies in the US and Europe. By referring briefly to their focus and history, the article reviews their standing in the field and its contribution to social sciences research methods generally.

Survey research draws on different disciplines. Insights from economics, sociology, psychology, statistics, geography, and other related subjects have all made their contributions to a highly interdisciplinary and cooperative field. The early roots of survey research might go back to the late nineteenth century; its takeoff, however, was not earlier than in the 1940s often supported by (radio) audience research and the American military during World War II. At the same time, the impact of some survey centers and companies for the development of survey research and their subsequent standing in the field cannot be overestimated. This article reviews eight centers and companies in three different countries. It distinguishes academic and public policy-driven survey research from survey research conducted by private companies. Although their difference is not clear-cut in practice, the application of academic methodological standards into the applied survey research process and the training and education of survey professional is what tends to distinguish survey centers from survey companies and justify such a distinction. Among the masses of survey centers and companies we will introduce four survey centers and companies as current 'blueprints' of contemporary survey research. These are, for (academic/national) survey centers the National Opinion Research Center (NORC, Chicago), the Institute for Social Research (ISR, Ann Arbor), the National Centre for Social Research (NATCEN, London), the Leibniz-Institute for the Social Sciences (German Social Science Infrastructure Institutes (GESIS), Mannheim) and for private survey companies Gallup (Washington D.C.), Westat (Rockville), Ipsos MORI (London), and Taylor Nelson Sofres (TNS) Emnid (Bielefeld). By presenting briefly their history and their contribution to survey research, this article will review their standing in the field and the future development of survey research. Since the emphasis is on survey research, this article will next give a short overview of what distinguishes surveys from other methods of data collection.

Survey Research – Definition and Brief Overview

Surveys are understood here as "a method to gather information from a sample of individuals" (Scheuer, 2004), using interviews as the source of information and systematic sampling as the base for selecting information sources (cf De Heer et al., 1999). They are instruments to identify distributions of societal characteristics. Questions or items in a survey are understood as indicators pointing to a latent construct (e.g., opinions, attitudes) or dimensions. Survey research is not interested in information about individuals. Instead, it is interested in information on larger groups, even societies. These target groups are termed populations. The information gathered by questioning individuals is used to make inferences to the population being studied.

At the first sight conducting surveys seems simple: it is basically about asking questions, recording answers and inferring characteristics, and dimensions from a small sample of individuals to a larger population. However, survey research is fairly complex. It involves specific methods and techniques of sampling and measurement. It has to deal with problems such as nonresponsiveness, social desirability bias, or construct validity. The way a question is worded, for instance, has subsequent effects on how a question is answered. To deal with these issues survey research has from its very beginning embarked on range of disciplines such as cognitive psychology and statistics. Apart from these methodological challenges survey research also involves organizational and administrative challenges. While a survey conducted in a closed classroom should not pose a greater problem for a survey researcher it looks entirely different when a survey is conducted in a national, regional, or even global space. This requires not only different methods how to reach the individuals that come with own problems but also enough interviewers to collect the data and a number of supervisors to oversee the whole process. This complexity requires adequate technical, organizational, and administrative capacities. Large commercial survey companies such as Gallup, Ipsos MORI, and RAND with various site offices and thousands of employees in numerous countries provide these capacities and are able to conduct large-scale cross-national surveys for the public and private sector. They partly compete with other large noncommercial (academic/national) survey centers of global research such as NORC, ISR, and GESIS that match these capacities.

Distinguishing Survey Centers from Companies

The survey industry can be thought of as compromising at least two distinct actors: survey centers and commercial firms.

What distinguishes these are basically whom they do research for and what type of research they do. While commercial survey companies largely have other private firms as customer, and concentrate on market research as well as research for media corporations, noncommercial survey centers serve mainly academic communities, governments, or public interests more in general. As such the latter engage more in methodological and long-term policy and social research. By definition commercial survey companies are more likely to sell the information gathered, while survey centers distribute the information mostly free to a wider public audience.

Noncommercial survey centers can be thought of as compromising two subtypes that are closely related: academic and national survey centers. In contrast to commercial survey companies, academic survey centers do not only promote rigorous methodological standards and perspective but they engage also in methodological research. Their research goes beyond the 'we use the method because it works to find out XYZ' as it also aims to find out 'why and how this method works to find out XYZ.' Academic survey centers, such as NORC, ISR in the US, GESIS in Germany, or RECSM in Spain are, thus, also known centers of methodological excellence. They often host long-term surveys and collaborations on national, regional, and international issues.

National survey centers focus mainly on domestic issues of public interest and collect information on public attitudes, opinions, demographic characteristics such as age, gender, urban/rural, and other characteristics of national residents. The NORC and the ISR in the US, the National Centre for Social Research (NATCEN) in the UK, the Norwegian Social Science Data Services, GESIS are prime examples and carry out major national surveys. Their annual studies, the General Social Survey (GSS, conducted by NORC), the German General Social Survey (conducted by ZUMA/GESIS), or the British Election Studies (conducted by NATCEN) feed into many social science research projects, and inform public policy making.

ZUMA and NORC are also founding members of the International Survey Programme (ISSP). The ISSP consists of cross-national collaborations that bring together numerous survey centers and projects, thereby adding a cross-national perspective to the individual, national studies (www.issp.org). The ISR, in turn, took the lead in conducting the World Value Survey (WVS). The WVS brings together a global network of social scientists and provides a cumulative study of almost 100 countries on changing values and their impact on social and political life. It is the largest ongoing, cross-national investigation of human beliefs and values (www.worldvaluessurvey.org).

Generally speaking, what differentiates survey institutions are primarily the target audience (private firms vs public agencies), the survey purpose, the publication of methodological research, the temporal aspect of the surveys (short-term vs long-term), and the free distribution of major nation-wide data sets. However, it might be noteworthy that these distinctions are not clear-cut in practice. In search for funding national and academic survey centers have also been charging fees for their services or set up own service centers within an academic department instead of relying only public research grants and contracts (Guterbock, 2010).

There are numerous survey centers and thousands of commercial survey companies across the globe. No reliable figure of their actual number exists. Since no other country has as many survey centers and companies as the US (Converse, 2009; Guterbock, 2010), this article will concentrate in particular on American centers and companies but makes reference to Europe.

Survey Centers

National Opinion Research Center, Chicago

NORC is one of the largest national survey centers in the US and is based at the University of Chicago (www.norc.org). It was established in 1941 as a nonprofit organization through a grant from the University of Denver and the Field Foundation. It moved to the Chicago campus in 1947. The center conducts research for public and private entities throughout the world. Its key areas of research focus on public issues such as health, education, economics, crime, justice, energy, security, and the environment. NORC is primarily known for its large national surveys and its innovations in survey methodology. Since 1972, NORC conducts the GSS. The GSS is funded by the National Science Foundation (www.nsf.gov) and is a general data-collection program that monitors the structure and development of American society over time (http://www3.norc.org/GSS+Website). It is one of the most frequent cited sources of information and, as such, has been for the benefit of the sociological profession at large. The GSS is released every year. Many of the core questions have been unchanged since 1972 to allow for time-trend studies. Interested parties have free access to historical and up-to-date survey material, which they can analyze on their own terms. Other strongholds of NORC are its methodological research on measurement errors.

Institute for Social Research, Ann Arbor

The ISR belongs to the University of Michigan and is the world's largest academic survey centers in the world (http://home.isr.umich.edu). It was established in 1949 and conducts research for the public and private sector. From its very beginning the ISR understood itself as a laboratory of and for the social sciences and advocated interdisciplinary research. Today it compromises five centers: The Center for Political Studies, the Inter-university Consortium for Political and Social Research, the Population Studies Center, the Research Center for Group Dynamics, and the Survey Research Center. The academics come from a broad range of fields including sociology, psychology, anthropology, economics, sociology, history, political science, and statistics. The ISR is known for its broad expertise on broad range of subject matter. Key areas of research focus include drug use, poverty, health, group processes and social cognition, aging, human development, political participation, voting behavior, institutions and political processes, and so on. The ISR has conducted groundbreaking methodological research and paved the way of modern survey research in areas such as survey sampling theories and methods and survey cognition processes. Among its major achievements are the development of the Likert Scale, one of the most widely used measure of attitudes and options academic, government,

and private sector research today and foundation of the field of organizational behavior. The ISR conducted several surveys which had major impacts on politics and society: In 1954, for example, it fielded the double-blind experimental trials for the Salk polio vaccine on a national sample of the US schoolchildren, revealing that vaccine was both safe and effective. Another impact area is data storage, education, and training. The Inter-university Consortium for Political and Social Research, which was founded in 1962, is one of the world's largest archives for quantitative social science data. It provides interested research access to thousands of data files. Moreover, it offers different education and training programs for graduates, postgraduates, and researcher in all phases of survey research. As such, the ISR contributes to secure and expand the existing knowledge base in survey methodology and methods.

National Centre for Social Research, London

The NATCEN is Britain's largest nonprofit survey research center. It counts about 250 employees and was founded in 1969 as charity governed by a Trust Deed (http://www.natcen.ac.uk). Its goal is to disseminate social, economic, and political research to the public for debate and educational purposes. NATCEN provides services to both the public and private sector agencies. Its customers include the UK government departments, think tanks, charities, businesses, universities, and other research organizations. The scope of NATCEN's research is broad and focus on issues such as health, demographics, crime, education, political attitudes, transport, income, and housing. Within the tradition of British social research NATCEN conducts quantitative and qualitative studies. Researchers at NATCEN have produced a range of highly applicable survey studies. Among their major accomplishments are the British Social Attitudes Survey (BSA), Britain's general social survey. The BSA has been carried out since 1983 and involves about 3000 in-depth interviews about what is like to live in Britain. BSA informs the development of British public policy and is well used by opinion leaders and social commentators as an important barometer of public attitudes. NATCEN forms the base for a number of mid-range and long-range programs and projects such as the Centre for Research into Elections and Social Trends. Funded by the Economic and Social Research Council the research center is a joint venture of the Department of Sociology in Oxford, on the one hand, and NATCEN on the other. The Scottish Centre for Social Research, in turn, is an integral part of NATCEN and conducts applicable social and political research reflecting the different social and political environment in Scotland. Apart from these projects NATCEN has recently launched its NATCEN learning platform, which provides training and education for interested researcher and the policy community interested in survey methods and methodology. It thus contributes to secure and boost the quality of applied survey research in the UK.

GESIS: Leibniz-Institute for the Social Sciences, Mannheim

With more than 250 employees GESIS is the largest social science research institute in Germany (www.gesis.org). GESIS was established in 1986 as the publicly funded German Social Science Infrastructure Services and consisted of a close collaboration between the three independent institutes: The Social Science Information Centre (IZ) in Bonn, Central Archive for Empirical Social Research in Cologne (ZA), and Centre for Survey Research and Methodology (ZUMA) in Mannheim. In 2007, they merged into one institute and rebrand itself as GESIS – Leibniz-Institute for the Social Sciences. GESIS is fully financed through public funds as provided by the federal government and the German Länder although foundations and other sponsors are increasingly involved in single project funding. Being primarily publicly funded GESIS is obliged to have a strict supportive function for academic research. Accordingly, the institute provides expertise in all production processes of social sciences research. Key areas of research concentrate on basic research in survey methodology, social research on attitudes, behavior and social structure, applied informatics and information sciences. Moreover, GESIS provides research-related services such as data storage, consulting, education and training in survey design, methods and archiving. All services are free or nominally charged. GESIS, as such, provides a comprehensive and unique infrastructure for academics and social sciences as a whole. Apart from the particular institutional design GESIS and its different organizational units have contributed in a range of large-scale surveys and cross-national projects. Among these are the ISSP, the European Social Survey, the German General Social Survey (ALLBUS) and the Programme for the International Assessment of Adult Competencies. The GESIS's Central Archive for Empirical Social Research (ZA), founded in 1960, is the German national archive for quantitative survey data and played a major role in establishing the international archive network. The Social Science Information Centre (IZ) keeps track of German social sciences publications, ongoing research projects and serves as a platform for information exchange between Eastern and Western Europe. GESIS is without doubt Germany's 'engine room' for social and political survey research.

Survey Companies

Gallup, Washington D.C.

Gallup is among the largest private market and opinion research companies of world (www.gallup.com). It is employee-owned and engages primarily in customized public opinion polling, market research, and consulting. Its clients are major businesses and organizations from around the world. Gallup employs around 2000 people and has offices in almost 40 countries. It was set up in 1935 by George Gallup in Washington D.C. Gallup was one of the first companies that engaged professionally and at large in survey research. It became suddenly famous in 1936 as it rightly predicted the victory of Franklin D. Roosevelt in the US presidential election, thereby contradicting the popular polls of that time that predicted a landslide victory for Alfred Landon. The company relied on a relatively small (5000 respondents) but carefully elected sample from the US population using face-to-face interviews instead of usual indiscriminate mail surveys that reached more better-off households and got it

right. Gallup was the first commercial survey organization using nation-wide probability sampling. Gallup's correct prediction had substantial influence on the practice of sampling. Gallup's methodology were copied not only in the US but in the emerging polling in Europe and Australia (Fink, 2003: 108). Gallup was also one of the pioneers engaging in global polling. In the early years the Gallup International Research Institute held annual meetings at which various affiliates reported and analyzed what the world's people thought about the multitude of sensitive and controversial issues that affected their lives such communism, capitalism, religion, etc. Since 2005, it conducts the Gallup World Poll bringing together survey data from more than 160 countries measuring attitudes, opinions, and trends. The insights have been used by different academic and public institutions such as the UN, the World Bank, or the OECD. Although Gallup regularly conducts political, social, and economic opinion polls and data analyses for large media corporations such as CNN or USA Today, market research has always been a second cornerstone of the corporation. Gallup moved more into business consulting in the 1990s as the company was purchased by Selection Research International in 1988 following the death of founder George Gallup. Today Gallup engaged also in employee engagement, customer engagement, talent management, and well-being using polls. It also issues its own journal, the *Gallup Business Journal* and has published several books. Some of the content and data produced by Gallup is free on its Web site or accessible via its customers, full data set is, however, only accessible via a paid subscription. Moreover, Gallup contributes to the Survey Research and Methodology program at the University of Nebraska-Lincoln through grants, fellow- and studentships.

Gallup's main contribution was to establish nation-wide probability sampling. Gallup experimented with different survey methods and helped establish surveys as a systematic method of data collection.

Westat, Rockville

Along with Gallup and other big corporations such as RTI International, RAND, Survey Sampling International, Nielsen, Opinion Research Corporation, and Abt Associates, Westat is one of the largest private survey companies of the US (www.westat.com). Westat was founded in 1963 by a professor and two former students. Its establishment and rise has its historical context in the massive demand for statistical information by the US government and businesses in the 1960s (Groves, 2011: 865). Today it employs around 2000 people at its headquarter in Rockville while it maintains several research offices in the US and abroad, in particular in Asia. Westat is employee-owned and conducts research for the public and the private domain. Among its customers are various departments and agencies of the federal US government but also foundations, businesses, states, and local governments. Key research areas concentrate on issues such as on health and medicine, education and literacy, social policy, workforce, recruitment and retention of military personnel. In addition to its survey research, Westat engages also in custom and evaluation research and communications development. Moreover it developed WestVar, a statistical software program. Westat has a broad expertise for all phases of survey research – sample design; instrument design; execution of mail, telephone, web, and personal interview data collection; data processing; analysis and report writing. Westat is well known for collecting the annual National Assessment of Educational Progress, the National Health and Nutrition Examination Survey, and the National Medical Expenditure Penal Survey which all inform the US public policy.

Ipsos MORI, London

Ipsos MORI is a leading private research survey company in the UK and was founded by a merger of Ipsos UK and MORI in 2005 (www.ipsos-mori.com). It is part of the Paris-listed Ipsos Group and, thus, part of one of the largest private survey research organizations in the world. Its offices distributed in more than 80 countries. Ipsos MORI conducts research for the public and the private sector. It is specialized in market research, media research, marketing and advertising research, reputation research, loyalty research, social and political research. Ipsos MORI investigates industry structures and trends, tries to understand what motivates and influence costumers and engages in research to test market products. It does so on a national and cross-national basis. Ipsos MORI's Social Research Institute is often consulted by the UK government and other major and smaller public and private authorities to inform public debate and decision making. It examines public attitudes toward key public services and provides information to assist social policy makers.

Researcher at Ipsos MORI uses a wide range of quantitative and qualitative methods. Ipsos MORI's predecessor RLS were leading way in using Computer-Assisted Telephone Interviews on a large-scale basis and were among first to use Computer-Assisted Personal Interviews. Moreover, RLS were among the pioneers in the development of regional surveys as The European Businessman Readership Survey, The Asian Businessman Readership Survey, and the British Businessman. Regional surveys involve an added complexity in terms of research design, database modeling, overseeing and coordinating the survey. MORI, instead, was known for its research on public attitudes to key public services that came with trends toward privatization and outsourcing of public services and its research on social policies and the trend of evidence-based public policy making. Ipsos MORI has been at the forefront of using new digital tools such as Internet surveys as well as mobile research and biometric tools.

TNS Emnid, Bielefeld

TNS Emnid is the oldest and one of leading private survey companies in Germany (www.tns-emnid.com). It was established in 1945 and serves since 1997 as the national branch of the larger London-based TNS Group, which is, in turn, owned by the London stock exchange-listed WPP Group since 2008. The WPP Group is by 2014 the largest market research holding of the world (www.wpp.com). TNS Emnid counts about 50 employees and conducts political, social, and media research. It does so primarily but not exclusively on the national level. To its customer belong major public entities and private organizations, including businesses, foundations, and other

survey research centers. TNS Emnid investigates political opinions and trends such as the weekly Sonntagsfrage ('Which party would you vote for if general elections would be held next Sunday?') and social issues such as crime, religion, cross-cultural attitudes and engages in advertisement research. TNS Emnid pioneered political opinion polling in postwar (West) Germany which became popular in the 1960s and has been frequently contracted by political actors and Germany's largest media corporations. Since 1955, TNS Emnid is member of the Gallup International Association and contributed to different of cross-national surveys such as the 'State of the Mankind' – study. TNS Emnid mostly known for its ad hoc polls following (inter-)national political events and uses primarily Computer-Assisted Telephone Interviewing and Computer-Assisted Personal Interviewing based on random dialing. More recently they have turned to mobile research tools and Internet surveys.

Conclusion: Surveys, Survey Centers and Companies, and the Social Sciences

Survey research centers are institutions that provide databases, methodological research, education and training for clients of the academic community, and are increasingly international in scope. Some academic survey centers such as ISR and GESIS have now combined social analysis, data archiving, storage, and information sciences to secure a functioning infrastructure of the social sciences at large.

More recently survey companies have shown a tendency to merge. Some of the originally national survey companies form now or part of large global survey groups as it is the case with Ipsos MORI and TNS Emnid mentioned above. Such global mergers cannot be observed in the academic realm, however. Instead, the smaller academic survey centers have created and relied on global networks and collaborations. These collaborations demand different capacities, require substantial financial means and might involve a future reconfiguration of the roles between survey centers and between survey centers and companies.

A challenge that might affect future survey research and their infrastructural carriers are the threats and opportunities that arise with the Internet. The Internet has enabled the collection in massive amounts of data (Big Data). Private survey companies have been at the forefront in using new modes of knowledge production such as Web-based tools or mobile research tools. Overall, it remains to be seen how survey research methods and techniques will change as Big Data approaches evolve.

Surveys and Polling: Ethical Aspects

Constance F Citro, Committee on National Statistics, National Research Council/National Academy of Sciences, Washington, DC, USA

© 2015 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by E. Singer, volume 22, pp. 15314–15318, © 2001, Elsevier Ltd.

Abstract

Polls and surveys gather data from respondents. Two broad aspects of ethical practice for them are: (1) the extent to which research designs, instruments, data collection procedures, and analysis techniques permit valid and reliable conclusions from respondents' answers; and (2) the researcher's obligations toward respondents, sponsors, and the larger public. The American Association for Public Opinion Research (AAPOR) Code of Professional Ethics and Practices defines best practices for survey research (e.g., scientific sampling) and unacceptable practices (e.g., selling under the guise of research). The World Association for Public Opinion Research (WAPOR) has similar ethical standards. Obligations to sponsors include documentation of methods used, and, increasingly for U.S. federal agency sponsors, sharing of research data. Obligations to the public include disclosing key information about the research (e.g., sponsor, size of sample). Obligations to respondents (embodied for research sponsored by U.S. federal agencies in Federal Policy for the Protection of Human Research Subjects, or Common Rule) include providing the opportunity for informed consent to participate and protecting the confidentiality of responses.

Polls and surveys are used to investigate opinions and attitudes and to obtain factual information from respondents. Two broad aspects of ethical practice with respect to polls and surveys can be distinguished. The first pertains to the extent to which research designs, instruments, data collection procedures, and analysis techniques permit valid and reliable conclusions from respondents' answers. The second pertains to the researcher's obligations toward others, not only toward respondents, but also toward sponsors and the larger public.

Polls and surveys are essentially indistinguishable, although the terms have somewhat different connotations. The word 'poll' is typically used for a survey of public opinion, such as whether the public thinks a president is doing a good job. This usage accords with another dictionary definition of 'poll,' which is 'the process of voting in an election.' The word 'survey' is typically used for a more comprehensive examination of one or more topics, such as a survey of household income and program participation or a survey of business research and development. This usage accords with a dictionary definition of 'survey' as 'to examine or look at comprehensively.' Because methodological issues of validity and reliability and issues of obligations of researchers toward others are the same, the present discussion of ethical practices is intended to apply to both polls and surveys.

While the discussion is framed primarily in terms of the code of ethics of one organization in a particular country – the Code of Professional Ethics and Practices (hereafter 'Code of Ethics') of the American Association for Public Opinion Research (AAPOR), a professional organization established in 1947, which includes academic, commercial, and government survey researchers among its members – the principles presented here apply more generally. Indeed, the World Association for Public Opinion Research (WAPOR), also established in 1947 with members in over 60 countries, has similar standards of ethics and good practices for opinion polls. (The WAPOR Code of Ethics was last revised in December 2011.) Because legal requirements for protecting respondent confidentiality and adhering to other ethical imperatives, as well as the ability to do so in practice, vary from one country to another, such variations are not discussed here. Also excluded from the discussion are the fundamentally different ethical issues raised by nonstatistical uses, such as law enforcement, program administration, or regulation, of data that were originally gathered from polls or surveys for statistical purposes (see National Research Council, 2013b; Seltzer and Anderson, 2008).

Standards for the Conduct of Research

AAPOR's Code of Ethics obligates members to adhere to the Code and includes provisions for reporting and reviewing violations, with appropriate punishment, including public censure. The Code, last revised in May 2010, is necessarily couched in general terms, simply asserting, for example, that members will "exercise due care in developing research designs and instruments, and in collecting, processing, and analyzing data, taking all reasonable steps to assure the reliability and validity of results." In May 1996, AAPOR adopted two more specific statements, one defining a set of performance standards that embody 'best practices' in survey research; the other, in contrast, defining a set of practices that are universally condemned. Among 'best practices' are scientific methods of sampling, which ensure that each member of the population has a measurable chance of selection; follow-up of those selected to achieve an adequate response rate; careful development and pretesting of questionnaires, with attention to known effects on response tendencies of question wording, question order, and interview mode (mail, telephone, Internet, in-person); and adequate training and supervision of interviewers. Among 'unacceptable' practices are fund raising, selling, or canvassing under the guise of research; representing the results of a poll of self-selected or volunteer respondents (for example, readers of a magazine who happen to return a questionnaire, callers to an 800- or 900-number poll, or haphazard respondents to a web-based survey) as if they

resulted from legitimate research; and 'push polls,' which feed false or misleading information to voters under the pretense of taking a poll. For example, a push-poll might ask if the respondent would object to learning that candidate X has been accused of child abuse, has defaulted on a loan, etc. Also among 'unacceptable' practices in the AAPOR Code are revealing the identity of individual respondents without their permission and requiring or soliciting monetary payments from members of the public as part of a research process.

Standards for Dealing with Sponsors, the Public, and Respondents

Obligations to Sponsors

Ethical behavior toward sponsors or clients has several elements, some of which apply to specific categories of sponsors. Applicable to all sponsors is the duty of researchers to undertake only those survey research assignments that can reasonably be accomplished, given the limitations of survey research techniques or limited resources of the researcher or sponsor.

Obligations to U.S. Federal Agency Sponsors

More and more federal agency sponsors are requiring timely sharing of research results and the underlying data, including survey data. For example, the data-sharing policy of the National Institutes of Health (NIH) requires all investigator-initiated grant applications of $500 000 or more in direct costs to propose a data-sharing plan that allows for 'timely release and sharing,' defined as 'no later than the acceptance for publication of the main findings from the final data set.' Final peer-reviewed journal manuscripts reporting on NIH-funded research are required to be accessible to the public via the digital archive PubMedCentral no later than 12 months after publication. Similarly, the data-sharing policy of the National Science Foundation (NSF) stipulates that "investigators are expected to share with other researchers, at no more than incremental cost and within a reasonable time, the primary data, samples, physical collections, and other supporting materials created or gathered in the course of work under NSF grants." In February 2013, the White House Office of Science and Technology Policy issued a memorandum on 'Increasing Access to the Results of Federally Funded Scientific Research,' which requires all federal agencies that annually fund over $100 million in scientific research to develop a plan for public access to digital data resulting from federally funded scientific research and a plan for public access to scientific publications, using a 12-month postpublication embargo period as a guideline. These policies all stem from the premise that federally funded data collections are of value to and should be 'made available to and useful for the public, industry, and the scientific community.' They all also recognize the imperative to maintain the confidentiality of individual responses as part of a data-sharing or public access plan (National Research Council, 2013b).

Obligations to Commercial or Private Sponsors

For commercial or other private sponsors, it is usually the case that the researcher has a duty to hold information about the research and the sponsor confidential, except as the sponsor expressly authorizes or as other provisions of the AAPOR Code require. Chief among the latter is a requirement that researchers who become aware of serious distortions of their findings in public must disclose whatever is necessary to correct these distortions to the audience to which the distorted findings were presented. In practice, this provision may obligate researchers to issue a corrective statement to a legislative body, a regulatory agency, the media, or another appropriate group as soon as they become aware of the release of distorted results. Moreover, increasingly, researchers who seek to publish findings from a commercially funded project in peer-reviewed journals should be prepared to secure the sponsor's agreement to allow the underlying data (suitably protected against disclosure of individual responses) to be shared with other researchers to permit verification and replication of results.

Obligations to the Public

The AAPOR Code of Ethics addresses the profession's obligations to the larger public by mandating the disclosure of information about a poll or survey whose findings are publicly released. (The Code obligates such information to be made available to a private sponsor at the time the results are delivered.) The elements that must, at a minimum, be disclosed are: (1) who sponsored the survey, and who conducted it; (2) the exact wording of questions asked, including text of any preceding instruction or explanation to the interviewer or respondent that might be expected to affect the response; (3) a definition of the population under study and a description of the sampling frame; (4) a description of the sample selection procedure, making clear whether respondents were selected by the researcher or were self-selected and whether probability or nonprobability methods were used; (5) the size of the sample and, if applicable, completion rates and information on eligibility criteria and screening procedures; (6) a discussion of the precision of the findings, including estimates of sampling error and a description of any weighting or estimating procedure used; (7) which results, if any, are based on parts of the sample rather than the entire sample; and (8) methods, locations, and dates of data collection. Together, these items of information communicate an idea of the error likely to be associated with estimates from a given survey, or, conversely, the degree of confidence warranted by the results. The Code requires much of this information to be included in or to accompany any report of research results, or, in some instances, to be available within 30 days of a request. In short, while the Code encourages researchers to follow best professional practices, it requires them to disclose the practices they used, relying on the 'marketplace of ideas' to drive out bad practices over time.

In the international arena, there are countries that impose barriers to release of public opinion polls. WAPOR has conducted five studies on the freedom to publish opinion polls – the first study included 49 countries and was conducted in 1984; the fifth and latest study included 85 countries and was conducted in 2012. The results of the 2012 study indicate that many countries impose embargoes on preelection and exit polls, presumably so as not to influence voting. More troubling, 12 countries indicated that there were legal or self-imposed bans on public opinion polls on particular topics, such as the

political leadership, religion or ethnicity, foreign policy, private matters (e.g., psychological problems), and values. Finally, about one-half of the 60 countries in which polls were frequently conducted indicated that access to poll results by researchers or the public was difficult or not possible.

Obligations to Respondents

Few, if any, surveys put respondents at physical or psychological risk in ways that psychological experiments or, particularly, medical research may do. Ordinarily, the biggest risk to survey respondents comes from the possibility that their identity will be disclosed, either inadvertently, because inadequate precautions were taken to maintain the confidentiality of the data, or deliberately, as a result of special efforts by an 'intruder' to obtain the identity of one or more respondents. Thus, survey organizations have a special responsibility both to protect the confidentiality of the data they collect and to inform respondents of the risks of disclosure that remain. Adding to the challenges of protecting confidentiality is the growing propensity of data collection programs to include not only traditional survey responses, but also such data as biospecimens (for example, blood or tissue samples) collected from respondents, geospatial information obtained from Internet sources and linked to respondents, and administrative records (for example, social security earnings records) linked to respondents. Yet another ethical issue pertaining to respondents arises from declining survey response rates and corresponding attempts to compensate by special persuasion strategies, including the offer of refusal conversion payments. Preceding the discussion of these issues is a brief summary of federal requirements for the protection of human research participants, including survey respondents. Although in the United States these requirements legally apply only to federally funded research that involves human subjects, many survey and polling organizations use institutional review boards (IRBs) to review new and ongoing survey projects to accord with federal requirements. In the international arena, the extent of regulation of research with human subjects varies from country to country. For example, member states of the European Union are subject to the provisions of the Clinical Trials Directive adopted in 2001, but this directive does not cover surveys or other noninterventional research.

U.S. Federal Agency Protections for Human Research Participants

The U.S. government first instituted policies designed to protect human research participants in the 1960s. These policies gained regulatory force in 1974 and evolved into the current "Federal Policy for the Protection of Human Subjects," Title 45 of the *Code of Federal Regulations*, Part 46. The Common Rule, as 45 *CFR* 46 is known, has been adopted by over 15 agencies and departments; it was largely put in place in 1991 with minor modifications in 2005 and 2009. All organizations that conduct research funded by a participating agency must register and operate an IRB to ensure that covered research complies with the Common Rule regulations.

A seminal document shaping the Common Rule was the 1978 report of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, known as the *Belmont Report* (see Citro, 2008; National Research Council, 2003). This report identified three major ethical principles for the conduct of research on humans:

- *Respect for persons*, or the obligation to treat people as autonomous agents by respecting their decisions on whether to participate in research. From this principle flows a requirement for researchers to obtain voluntary informed consent from participants, with special protective procedures when dealing with people who are immature, incapacitated, or whose autonomy is constrained.
- *Beneficence*, or the obligation to protect participants from harm to the extent possible and to maximize benefits that are likely from the research, not only for them, but also for society. From this principle flows a requirement for researchers and IRBs to assess risks of harm and probability of benefits in a systematic manner, including risks of disclosure of confidential information.
- *Justice*, or the obligation to show fairness in the selection of research participants with regard to who bears the burden of research and who benefits from the results.

Provisions of the Common Rule that are relevant to surveys and polls include:

- 'Research' is defined to include not only production but also pilot testing.
- Surveys or interviews are exempt from IRB review if they record responses so that individuals cannot be identified, directly or through identifiers linked to them, and if any reidentification would not reasonably be expected to place respondents at risk of criminal or civil liability or be damaging to their financial standing, employability, or reputation.
- Surveys or interviews are exempt from IRB review if their respondents are elected or appointed public officials or candidates for public office.
- Surveys that are not exempt may qualify for expedited IRB review if they present no more than 'minimal risk' to respondents as defined in the regulations.
- Surveys, like other research with human participants, must obtain the informed consent of individuals to participate, via written consent documents unless the IRB determines that the existence of a signed written consent could lead to a breach of confidentiality or the research is minimal risk and involves procedures for which written consent is not normally required outside the research context.
- Surveys conducted with prisoners or children are subject to additional rules for protection of these vulnerable population groups.

A major overhaul of the Common Rule was proposed in an Advance Notice of Proposed Rule-Making, issued in July 2011 (see National Research Council, 2014). The goals of the proposed modifications are "to enhance the effectiveness of the research oversight system by improving the protections for human subjects while also reducing burdens, delays, and ambiguity for investigators and research subjects." As of this writing, no action has been taken to finalize the proposed changes.

Other federal laws may affect surveys that plan to link administrative records to survey responses. They include the Family Educational Rights and Privacy Act of 1974 (FERPA, 34

CFR 99), which governs the use of school-based records, and the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and the accompanying Privacy rule issued by the U.S. Department of Health and Human Services (DHHS) in 2002 (45 *CFR* 160, 164), which govern use of patient medical records.

Informed Consent in Surveys and Polls

Informed consent means that a person's decision to participate is made by that person (or his or her legally authorized representative), without pressure to hurry decisions, coercion, or undue influence from the researcher, and with relevant, understandable information about the research (National Research Council, 2003). One important purpose of informed consent is to protect respondents from harm. Another purpose is to give them meaningful control over information about themselves, even if the question of harm does not arise. For example, informing potential respondents of the voluntary nature of their participation is essential to ethical survey practice, even if this leads some potential respondents to refuse to participate. (All private sector and all government surveys of households and individuals in the United States are voluntary, with the exception of the decennial census and the American Community Survey conducted by the U.S. Census Bureau under the authority of Title 13 of the U.S. Code and the U.S. Constitution.) Similarly, obtaining respondents' permission to record an interview should be standard practice, even though no harm is likely to come to them as a result.

At present, obtaining informed consent is only legally mandated for surveys funded by federal agencies under the Common Rule and subject to IRB approval. For the many other surveys conducted for nonfederal sponsors, the AAPOR Code of Ethics mandates that researchers "provide all persons selected for inclusion with a description of the research study sufficient to permit them to make an informed and free decision about their participation, … make no false or misleading claims as to a study's sponsorship or purpose, and … provide truthful answers to direct questions about the research. If disclosure could substantially bias responses or endanger interviewers, it is sufficient to indicate that some information cannot be revealed or will not be revealed until the study is concluded." (The American Sociological Association Code of Ethics, adopted in 1999, also includes a requirement to obtain informed consent.) The AAPOR Code further mandates that researchers "avoid practices or methods that may harm, endanger, humiliate, or seriously mislead survey respondents or prospective respondents" and that researchers "respect respondents' desires, when expressed, not to answer specific survey questions or provide other information to the researcher." Similarly, the American Statistical Association (ASA) Ethical Guidelines for Statistical Practice, adopted in 1999, cautions researchers to avoid excessive imposition on the time and privacy of respondents and also to use no more (or less) numbers of research subjects to satisfy the study requirements for precision of results.

Historically, a point of contention of the survey research community with IRBs has been the preferred status in the Common Rule accorded to written consent. Research has demonstrated that a small but significant group (around 10%) of potential respondents is willing to participate in a survey but not to sign a consent form (Singer, 2003). Consequently, IRB insistence on written consent in minimal-risk surveys does not appear to protect respondents and can reduce the generalizability of the findings. The National Research Council (2003) supports the waiver of written consent by IRBs as a matter of routine for mail and Internet surveys of the general population and most telephone surveys, primarily because the interaction between the interviewer and respondent is absent or at arm's length, and the respondent can easily choose not to respond. For in-person interviews, the National Research Council finds that tacit consent (that is, willingness of the respondent to sit for the interview) is usually adequate. For a more-than-minimal-risk survey, explicit consent is appropriate, although it is possible that verbal consent is preferable to written consent if the existence of a paper record could intentionally (by subpoena) or accidentally become public and cause harm to the respondent. Finally, additional separate consent procedures are likely to be required when a survey is to collect biospecimens that will be stored for future research and when survey responses are to be linked to administrative records or other independent data sources.

Protection of Respondents' Confidentiality

As noted above, probably the most important source of risk and potential harm to survey respondents comes from identification of their responses – that is, from deliberate or inadvertent breaches of confidentiality. The more sensitive the information requested – for example, HIV status or whether the respondent has engaged in some illegal activity – the greater the harm that a breach of confidentiality might entail. Not unexpectedly, respondents require strong assurances of confidentiality when they are asked to provide such data about themselves (Singer et al., 1995). There is also evidence of rising public concerns about confidentiality and privacy, which is problematic for maintaining survey response rates given the finding that people with stronger concerns in this area are less likely to participate in surveys (Singer et al., 2003).

A variety of threats to the confidentiality of survey data exist (National Research Council, 2005). Most common is simple carelessness – not removing identifiers from questionnaires or electronic data files, leaving cabinets unlocked, or not encrypting files containing identifiers. Although there is no evidence of respondents having come to harm as a result of such negligence, it is important for data collection agencies to be continually vigilant to raise the consciousness of their employees with respect to these issues, provide guidelines for appropriate behavior, and ensure that these are observed.

Less common, but potentially more serious, threats to confidentiality are legal demands for identified data, either in the form of a subpoena or as a result of a Freedom of Information Act (FOIA) request. Surveys that collect data about illegal behaviors such as drug use, for example, are potentially subject to subpoena by law enforcement agencies. To protect against this, researchers studying mental health, alcohol and drug use, and other sensitive topics, whether federally funded or not, may apply for Certificates of Confidentiality from DHHS. Such certificates, which remain in effect for the duration of the study, protect researchers from being compelled in most circumstances to disclose names or other identifying characteristics of survey respondents in federal, state, or local proceedings (42 *CFR* 2a.7, 'Effect of Confidentiality

Certificate'). The Certificate protects the identity of respondents; it does not protect the data, nor will it protect against 'statistical disclosure' discussed below.

When surveys are done expressly for litigation, demands for data from one party or the other are not uncommon, and protection against such demands may not be available. Several such cases are reviewed by Presser (1994). In one, the case was settled before the data were to be produced; in two others, the courts ordered the researchers to turn over raw data, including respondent identifiers, to the defendants. Presser (1994) discusses several actions that might be taken by professional survey organizations to enhance protection of confidentiality in such cases – for example, mandating the destruction of identifiers in surveys designed for adversarial proceedings.

A final threat to data confidentiality that has become much more serious since the advent of the Internet is what is known as 'statistical disclosure.' There is increasing awareness that even without explicit identifiers, such as name, address, or social security number, reidentification of respondents may be possible given the existence of high-speed computers, external data files readily available on the Internet to which the survey data could be matched, and sophisticated matching software. Longitudinal studies may be especially vulnerable to such reidentification because of the breadth and depth of data typically available on each respondent. Both cross-sectional and longitudinal studies are also more vulnerable to the extent that the data collection includes links to administrative records or other data sources. Finally, not only data provided in aggregate form, but also and especially microdata records for individual respondents are vulnerable to reidentification.

There are several ways to reduce the risk of statistical disclosure. For microdata, one method is to restrict access, for example, by requiring researchers to work in research data centers or enclaves, such as those maintained by the U.S. Census Bureau at a number of universities, or by requiring researchers and their institutions to agree to the terms of a license for access to microdata at their own site or through electronic communication to sites that house the data in a secure environment. For both aggregate and microdata, another way to reduce risk is to restrict the data that are released, for example, by top-coding age and income and releasing detailed data only for large geographic areas. Yet a third way to safeguard aggregate or microdata is to create synthetic data derived from respondents' actual information by using multiple imputation and other sophisticated statistical methods. There are tradeoffs for the researcher in each of these forms of access (see Duncan in National Research Council, 2003; Federal Committee on Statistical Methodology, 2005; for special issues for surveys that collect biospecimens, see National Research Council, 2010).

In view of the diverse threats to confidentiality reviewed above, there is growing consensus among researchers that absolute assurances of confidentiality should seldom, if ever, be given to respondents. The ASA Ethical Guidelines, for example, caution statisticians to "anticipate secondary and indirect uses of the data when obtaining approvals from research subjects." At a minimum, the Guidelines urge statisticians to provide for later independent replication of an analysis by an outside party. They also warn researchers not to imply protection of confidentiality from legal processes of discovery unless they have explicit authorization to do so, for example, by a Certificate of Confidentiality. Research by Singer et al. (1995) suggests that for surveys on nonsensitive topics, neither the response rate nor data quality is likely to suffer as a result of such qualified assurances of confidentiality.

Efforts at Persuasion

A third ethical issue concerning respondents is the dilemma created by the need for high response rates from populations that spend less time at home, have less discretionary time, and are less inclined to cooperate in surveys (National Research Council, 2013a). The problem of falling response rates leads survey organizations to greater use of incentives to promote response, which research shows generally improves cooperation (Singer and Ye, 2013), and to more follow-up attempts for respondents who do not respond to the initial contact attempt, often using different methods, such as telephone follow-ups to a mail survey. The problem also leads survey organizations to attempt more conversions of people who actually refuse to participate and to make greater use of refusal conversion payments. Respondents see both practices as undesirable (Groves et al., 1999). They also regard the paying of refusal conversion payments as unfair, but awareness of such payments does not appear to reduce either the willingness to respond to a future survey or actual participation in a new survey (Singer et al., 1995). Surveys are increasing turning to so-called 'responsive design,' whereby models and paradata about incoming responses are used to determine which nonrespondents it is most cost-effective to pursue.

Polling on the Net

Polls and surveys conducted on the Internet have shown explosive growth in the last several years, and such surveys not only bring entirely new ethical problems to the fore, but also new dimensions to old problems. For example, maintenance of privacy and confidentiality in such surveys requires technological innovations (for example, 'secure' Websites, encryption of responses) beyond those required by older modes of data collection. Other ethical issues arise for Internet surveys that have never pertained to older modes of conducting surveys – for example, the possibility that a respondent might submit multiple answers, thus deliberately biasing the results – and these, too, call for new technical solutions requiring sophisticated knowledge of computer hardware and software. These problems, and proposed solutions, are still too new to permit more than brief mention of them here.

Concluding Observations

A number of developments in recent years have increased ethical dilemmas for survey researchers. There is growing demand for information about individuals on the part of both business and government. At the same time, there is growing concern about personal privacy on the part of the public. Technological developments have made safeguarding privacy and confidentiality increasingly difficult, and for this as well as other reasons, there is increasing reluctance on the part of the public to participate in polls and surveys, including

government censuses. How these dilemmas are resolved in the next decade will have profound implications for the future of survey research.

Surveys: Extreme Response

Daniel M Bolt, University of Wisconsin-Madison, Madison, WI, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Extreme response style (ERS) is a frequently observed response style in which respondents disproportionately select the extreme end points of a rating scale (e.g., 1 = strongly disagree and 7 = strongly agree on a 7-point Likert rating scale). ERS has been demonstrated to contribute to bias in the measurement of latent constructs and in estimates of their association with other variables. It frequently correlates with other person and survey-related variables, and has also been shown to vary in its prevalence across cultures. Different statistical methods for both measuring ERS and controlling for the biasing effects of ERS have been presented in the research literature.

Rating scales in survey measures are often used in unique ways by different respondents. Response styles (alternatively 'response sets') refer to stylistic tendencies in how respondents assign ratings to items unrelated to item content (Cronbach, 1946). Response styles are often reflected by disproportionate tendencies toward using particular rating scale categories. A common form of response style that has been the focus of much methodological research is 'extreme response style' (ERS). ERS is defined by the tendency to select the extreme end points of a rating scale (such as 1 = 'strongly disagree' and 7 = 'strongly agree' on a 7-point Likert scale). Although various response style types have been documented, ERS has likely received the largest amount of attention in the research literature. This is probably due both to the high frequency with which it is observed as well as its demonstrated tendency to correlate with both person- and survey-related variables. The observation of ERS in a survey often coincides with the observation of an 'anti-ERS' response style, namely, a disproportionate tendency to avoid the extreme end points.

Different explanations have been given for the occurrence of ERS (Baumgartner and Steenkamp, 2001), some of which may be more relevant than others depending on the context. To the extent that response styles are often viewed as relatively stable characteristics of persons, the explanations have often focused on person-related variables, although characteristics of the survey, or an interaction between person and survey features likely also play a role (see below). One explanation is that ERS behavior is the manifestation of a personality characteristic or trait of the respondent, such as an intolerance of ambiguity (Naemi et al., 2009), for example. A related explanation focuses on different response norms, as might be associated with different cultural backgrounds, for example, whereby some respondents are encouraged to respond in modesty (i.e., anti-ERS) and others to respond in sincerity (i.e., ERS) (Hui and Triandis, 1989). Such explanations would appear to apply best to self-report surveys. Yet another common perspective connects ERS to a respondents' attempt to simplify the process of responding to multicategory items. Distinguishing between multiple levels of agreement to a survey item, such as on a 7-point rating scale, for example, can be cognitively demanding, especially when applied repeatedly across a large number of items. From this perspective, respondents may only choose among rating scale end points as a way of reducing the complexity of the response process to a more simple agree/disagree response. Such an explanation appears consistent both with the relationships seen between ERS and more simplistic thinking/faster response times (e.g., Naemi et al., 2009), and the tendency to observe higher levels of response style behavior on surveys carrying more substantial cognitive load (Van Vaerenbergh and Thomas, 2012).

Consequences of ERS

ERS can be viewed as a form of systematic measurement error that contributes to bias in survey scores. Depending on the use of the survey instrument, the bias introduced can have significant consequences both in the interpretation of individual scores and in evaluating how the intended-to-be-measured substantive trait relates to other variables. At the individual level, ERS can systematically bias survey scores upward or downward depending on the substantive trait level of the respondent and the difficulty levels of the items (Baumgartner and Steenkamp, 2001; Bolt and Johnson, 2009). As a simple example, for a respondent whose expected response to an item (based on substantive trait level only) would be a 6 on a 1–7 scale, the presence of ERS will likely lead the respondent to select a 7 as opposed to a 6 (upward bias), while for a respondent whose expected score to an item (based on substantive trait level only) is a 2, ERS will likely lead to selecting a 1 (downward bias). ERS can also bias estimates of the distributional characteristics of the substantive trait across groups, such as in cross-cultural comparisons of scale scores. For example, Mõttus et al. (2012) evaluate ERS as a possible cause of unexpected country-level differences in self-reported levels of conscientiousness. Along these lines, ERS can also bias estimated associations between the survey and other external variables, a consequence that is also related to the tendency for ERS behavior to correlate with other person variables (see below). For example, Moors (2012) illustrates the deleterious effects of ERS on the estimated correlations among various leadership style types. In addition, the presence of ERS can interfere with the study of other psychometric properties of tests and test items, such as the study of differential item functioning/measurement invariance across groups (Morren et al., 2011; Bolt and Johnson, 2009). For these reasons, it

can be important to evaluate the potential effects of ERS on survey scores, and where possible, correct for such effects.

Index-Based Measurement of ERS

Various approaches have been taken to measure ERS. The different approaches often represent subtle differences in how ERS can be formally defined. A common strategy is to construct an index directly based on the scores a respondent assigns to items. Examples of such indices include the proportion of times a respondent selects the extreme categories, or alternatively, the standard deviation of the ratings assigned by the respondent across items. A limitation of index methods is their likely sensitivity to a respondent's substantive trait level. For example, a respondent with an extremely high level on the substantive trait (e.g., an extreme attitude) may be selecting primarily extreme categories due to the intended-to-be-measured substantive trait and not due to ERS, which by definition is response behavior unrelated to item content.

As a result of this limitation, a more attractive alternative is to add additional self-report items solely for the purpose of measuring response style (Greenleaf, 1992). An ERS index can then be computed as above using only the added items. Ideally, the added items will tap constructs poorly related to the trait intended to be measured, so as to ensure that the ERS index serves as a purer indicator of response style. Such an approach assumes ERS to be a relatively stable characteristic of a respondent across constructs. A challenge in implementing the method involves identification of such added items, as in many disciplines it can be difficult to find constructs that are nearly uncorrelated. A promising approach that overcomes the limitation of the Greenleaf strategy is the use of anchoring vignettes. Anchoring vignettes are brief hypothetical scenarios that are rated by respondents using the same rating scale as is used for the survey instrument. The primary difference from the Greenleaf approach is that the vignettes do not relate to a self-report construct, and instead reflect scenarios designed to instill a common subjective response across all respondents. The administration of vignettes aligned with different levels of the rating scale can thus lead to insight in how respondents of varying trait levels are using the rating scale differently. While appealing, the method does assume that respondents use the rating scale in the same way for self-report ratings as when responding to the anchoring vignettes (King et al., 2004).

Psychometric Modeling of ERS

Another way of overcoming the limitations of index-based ERS measurement is to apply an item response model. There have been a number of different item response models advanced for the measurement of ERS. In describing the different models, it can be helpful to distinguish those that attempt to address response styles more generally from those that handle ERS as a qualitatively distinct response style type. An example of the former is Rossi et al.'s (2001) scale heterogeneity model. Under the scale heterogeneity model, individual differences in the use of ratings scale categories are captured by respondent-specific location (τ) and scale (σ) parameters, corresponding roughly to the mean and variance of ratings assigned across items. Such an approach can be viewed as addressing a wide variety of potential response style types, in this case all that can be understood by a linear translation of the rating scale. Under such an approach, ERS respondents emerge as respondents having large positive σ parameters. Such models can also be generalized to include respondent-specific category threshold parameters, in which case ERS respondents would tend to have thresholds for the extreme categories pulled much closer to the center of a subjective continuum. An approach of this kind is presented by Johnson (2003).

A different class of modeling approaches emphasizes ERS as a particular type of response style. These models associate with certain respondents a greater propensity toward selecting the extreme categories, specifically, as opposed to a general variability in item scores, and thus provide a more direct representation of ERS as traditionally defined. Such tendencies can be captured through latent class models, for example (Moors, 2003; Van Rosmolen et al., 2010), whereby different classes are defined by different response style types. Under such approaches, an ERS class commonly emerges in an exploratory analysis. Under the Moors (2003) approach, specifically, the latent classes emerge in the context of a latent class factor model, whereby one latent class factor corresponds to the intended substantive trait, and others to response style tendencies. Bolt and Johnson (2009) consider a continuous generalization of the Moors (2003) latent class factor approach. As in the Moors (2003) model, the item response is influenced simultaneously by the underlying substantive trait as well as an ERS trait that are related to the probability of selecting a particular score category using a multinomial logistic link function. For purposes of illustration, the author considers the Bolt and Johnson (2009) approach in more detail. Assuming $U_j = k$ to denote the event that a respondent selects score category k on item j, the probability of that event is given by

$$P(U_j = k|\theta_1, \theta_{\mathrm{ERS}}) = \frac{\exp\left(a_{jk1}\theta_1 + a_{jk,\mathrm{ERS}}\theta_{\mathrm{ERS}} + c_{jk}\right)}{\sum_h \exp\left(a_{jh1}\theta_1 + a_{jh,\mathrm{ERS}}\theta_{\mathrm{ERS}} + c_{jh}\right)}$$

where θ_1 and θ_{ERS} denote the continuous substantive and extreme response style latent traits, respectively (often assumed bivariate normal with a mean of 0 on each trait). In this model, the category slope parameters (for a seven-category item) are specified as a_{jh1}=(0, 1, 2, 3, 4, 5, 6) and $a_{jh,\mathrm{ERS}}$=(1, −0.4, −0.4, −0.4, −0.4, −0.4, 1), while the c_{jh} category intercept parameters are estimated but subject to a normalization constraint $\sum_h c_{jh} = 0$. Specification of the category slope parameters permits identification of the traits as conforming to the substantive and ERS traits, respectively.

The Bolt and Johnson (2009) model can be viewed as a multidimensional generalization of the nominal response model (Bock, 1972). As such, the model can be understood in a 'divide-by-total' framework where the numerator defines a respondent's propensity toward score category k, while the denominator captures the sum of propensities across all score categories. As a result, respondents with higher levels of

θ_1 are more prone to select the higher score categories (assuming items have been coded such that higher scores reflect a higher level of the substantive trait) and respondents with higher levels of θ_{ERS} are more prone to select the end-point categories.

Table 1 displays examples of item response patterns and estimated levels of ERS when the data are fit using the Bolt and Johnson (2009) and Rossi et al. (2001) models. The example item response patterns are from an analysis reported in Bolt and Johnson (2009) to a 68-item survey instrument measuring tobacco smoking dependence where each item is scored using a 7-point rating scale. Response patterns representing varying levels of ERS are shown, with Respondents 1 and 2 showing evidence of anti-ERS, Respondents 3 and 4 neither anti-ERS nor ERS, and Respondents 5 and 6 ERS. As seems apparent from these examples, both the scale heterogeneity (e.g., Rossi et al., 2001) and response style type-based (Bolt and Johnson, 2009) models of ERS generally provide comparable descriptions of respondents in term of their ERS tendencies. Importantly, both models are able to detect ERS tendencies for respondents across varying levels of the substantive trait.

Latent class representations of response styles can also be incorporated into models that characterize the substantive trait as continuous. Mixture item response models (e.g., Mixture Rasch models) provide a common statistical methodology in which such an approach can be applied (see e.g., Eid and Zickar, 2007). Under such models, class differences are commonly represented in the form of different thresholds associated with rating scale categories across items. ERS is seen through a class that has thresholds associated with the extreme categories that imply a greater tendency to select those response categories. Figure 1 displays latent class profiles for a mixture Rasch solution applied to data from a 10-item scale measuring the sixth graders enjoyment of science. The survey was administered as part of the Programme for International Student Assessment (PISA) 2003 survey (Bolt and Newton, 2011). All items were coded using four score categories ranging from 1 = strongly agree to 4 = strongly disagree. In the current analysis, a mixture partial model was applied that assumed a constant shift in the category threshold parameters associated with rating scale categories across items. Statistical criteria identified a three-class solution as superior. (Based on model coding, higher category estimates correspond to an increased likelihood of selecting the category.) The three classes that emerged reflect unique forms of response style, including an ERS class (class 3), an anti-ERS class (class 2), and a class with a disproportionate tendency to select category 4 (class 1), potentially a disacquiescent response style class.

Figure 1 Category thresholds associated with three class mixture partial credit solution, 2003 PISA survey measuring enjoyment of science (sixth grade).

Table 1 Example item score patterns from smoking dependence scale illustrating different levels of ERS behavior and measurement of ERS under different statistical models

Respondent	*Response pattern*	$\hat{\theta}_1$	$\hat{\theta}_{ERS}$	$\hat{\tau}$	$\hat{\sigma}$

One of the appealing aspects of item response models for ERS is not only their capability to measure ERS, but also their potential in controlling for the biasing effects of ERS on estimates of the substantive trait. This possibility is described in a later section.

Evaluating the Biasing Effects of ERS

Another advantage of a model-based approach to ERS is the ability to examine more specifically how ERS contributes to bias in survey scores. The author considers this issue again using the model of Bolt and Johnson (2009) as an example. For any given levels of θ_1, θ_{ERS}, one can initially compute an expected total score on the survey as

$$\text{Expected Score } (\theta_1, \theta_{\text{ERS}}) = \sum_{j=1}^{N} \sum_{h=1}^{n} k \times P(U_j = k | \theta_1, \theta_{\text{ERS}})$$

where $P(U_j = k|\theta_1,\theta_{\text{ERS}})$ is as defined in the previous section, and N and n denote the total number of items and rating scale categories, respectively. If one assumes the mean of θ_{ERS} (=0) to define an appropriate reference point, one can also use the equation to determine an expected score at this level of ERS, namely, Expected Score $(\theta_1,\theta_{\text{ERS}} = 0)$. Then bias can be estimated as

$$\text{Bias}(\theta_1, \theta_{\text{ERS}}) = \text{Expected Score } (\theta_1, \theta_{\text{ERS}}) - \text{Expected Score}(\theta_1, 0)$$

It is important to note that since there exists no 'correct' level of ERS, $\theta_{\text{ERS}} = 0$ is to some extent an arbitrary reference point. However, as the location represents the mean of θ_{ERS}, and due to the likely presence of both ERS and anti-ERS response styles, it provides a natural reference point. In addition, because survey scores will be strictly increasing in relation to θ_1 for any specified level of θ_{ERS}, any alternative θ_{ERS} reference location should lead to a similar result in terms of relative bias when comparing respondent scores.

An examination of bias curves allows for an evaluation of the practical influence of ERS on a survey. Figure 2 presents curves that illustrate the bias in total score for different levels of θ_{ERS} again in reference to the tobacco smoking dependence survey analyzed in Bolt and Johnson (2009). In this case, the y-axis illustrates average bias at the item score level. The curves make apparent how the biasing effects of ERS are dependent on θ_1. It is also important to note that these curves are dependent on the category intercept estimates of the items (not shown here), which will naturally vary across survey instruments. For the survey that is the focus of the current analysis, an appealing feature of the bias curves is that they consistently go to 0 at a θ_1 level of approximately 0.2, a location very near the mean of θ_1. As a larger number of respondents are located near the mean, it is apparent that for many respondents, ERS has very little biasing effect. Such a result can be attributed to the fact that for respondents near this trait location, there are nearly as many items with expected scores below 4 as there are items with expected scores above 4, leading to a cancellation of ERS bias effects across items. For other survey instruments, this naturally may not be the case, making plots such as those in

Figure 2 Bias due to ERS as calculated using Bolt and Johnson (2009) model, 68-item smoking dependence scale.

Figure 2 useful to inspect in determining the consequences of ERS.

Factors Related to ERS

A substantial amount of research has examined variables connected to display of ERS. ERS is frequently linked to person characteristics. For example, prior research has shown that respondents of higher education levels and socioeconomic status are often less prone to display ERS (Meisenberg and Williams, 2008) while respondents of more advanced age are more likely to display ERS (Kieruj and Moors, 2013). Other personality characteristics, such as trait anxiety (Lewis and Taylor, 1955), extraversion, and conscientiousness (Austin et al., 2006) have also been positively correlated with ERS, although findings across studies in regard to these factors are not always consistent (Van Vaerenbergh and Thomas, 2012). The effects of such respondent characteristics frequently align with explanations for ERS as given earlier, especially when viewing ERS as a stable person characteristic.

ERS has perhaps been most extensively studied in regard to its variability across ethnicity and culture. For example, some evidence suggests that respondents from Asian countries are less prone to display ERS, while those of Mediterranean or Latin American countries display on average higher levels of ERS. Similar effects are also seen across ethnic groups within a country (e.g., Marin et al., 1992). As noted earlier, one explanation for such findings may involve the application of different response norms across cultures (Hui and Triandis, 1989). Relatedly, Johnson et al. (2005) point to cross-cultural variability in the dimensions of masculinity and power distance as factors. To the extent that country-level comparisons of ERS are not always consistent, it is also possible that the content of surveys elicit stronger reactions in one culture compared to another, in which case cross-cultural differences that emerge as ERS might not be viewed as a response style

difference at all. Still other explanations for cross-cultural differences relate to issues associated with the translation of anchor points on rating scales or wording of items (Arce-Ferrer, 2006). Given the increased use of cross-cultural assessments and appeal in studying cultural differences in the social sciences, attempting to understand and address ERS in this context is an important area of future research.

While the response style literature has tended to emphasize response styles as stable person characteristics, there is also evidence that response style tendencies can become more prominent in some contexts than others. For example, to the extent that a respondent has a higher level of involvement with a topic, ERS can be increased (Gibbons et al., 1999). Other moderating factors may relate to characteristics of the administration of items and/or rating scales. One potentially relevant factor is the number of rating scale points, with some evidence suggesting scales with more scale points, as well as scales that include a middle point, can be less prone to lead to ERS (Weijters et al., 2010). In addition, administering items using a two-stage approach, whereby an initial filter item (e.g., agree/disagree) is followed by a subsequent item reflecting intensity (e.g., extent of agreement), has at times been shown to increase ERS, but in other contexts to decrease it (see e.g., Albaum et al., 2007). Other studies have examined the format of administration, such as Web-based versus paper/pencil-based responding, where Web-based administration is often seen to lead to greater ERS (e.g., Heerwegh, 2009). Although (as with person characteristics) there is a fair amount of inconsistency in the literature regarding the effects of characteristics of the survey instrument on ERS, most research appears supportive of some general principles in minimizing response style effects. As a general rule, the more that can be done to reduce the ambiguity of the responding process, the more likely the effects of response style, including ERS, are reduced. Reduced ambiguity can be achieved in various ways, including more explicit rating scale anchor labels ('every day' as opposed to 'frequently,' for example), more labels attached to the rating scale, and careful wording of items so as to avoid ambiguity. In addition, attempts to reduce the cognitive demand of responding (e.g., fewer items) or else instill greater effort on the part of respondents can also be effective.

Methods for Correcting ERS Bias

Under conditions where ERS is detected and found to contribute to bias, various statistical techniques can also be used to correct the bias. When using an index-type method to quantify ERS, a common approach applies a simple linear correction to the scale score. Such a correction can be applied, for example, through a linear regression of scale scores on the ERS index and using the residuals of the regression in place of the original scale scores in subsequent analyses. One limitation of this strategy is that it assumes a constant biasing effect of ERS on the scale score, a highly questionable assumption (Baumgartner and Steenkamp, 2001). As seen in **Figure 1**, the biasing effects of ERS can clearly vary as a function of the substantive trait level of the respondent. A second limitation is that the approach fails to account for the possibility that ERS may correlate with the intended-to-be-measured substantive trait. As a result, the method can lead to an 'overcorrection' for ERS bias by removing that association.

As an alternative, many of the statistical models for ERS described earlier also implicitly perform a bias correction by including the substantive trait in the model. For example, in the Bolt and Johnson (2009) model, estimates of the θ_1 trait can be viewed as bias-corrected, given the simultaneous presence of the θ_{ERS} trait in the model underlying the item scores. A challenge with these types of strategies, however, is the frequent difficulty in disentangling the potential effects of ERS from the effects of the substantive trait on the item responses. Often, large standard errors are found for estimates of θ_1 in such statistical models, for example, in relation to a response pattern where only the highest rating scale categories are endorsed for all items.

Such limitations point to the value of anchoring vignettes, as described earlier. Some studies have illustrated potential ways in which responses to vignettes can be used to perform bias corrections. One approach uses vignette responses to define respondent-specific threshold locations for score categories that can then be applied in reference to the self-report responses (King et al., 2004). In effect, the method attempts to reproduce the relative spacing and location of rating scale categories corresponding to the respondent's own internal representation of the rating score categories against a subjective continuum. A related approach makes use of vignette responses within a hierarchical ordinal probit (hopit) model, where bias corrections are performed in the context of relating the self-report items or survey scores to other variables (Grol-Prokopczyk et al., 2011). Each of these methods is more consistent with a scale heterogeneity approach to modeling response styles, and thus would be implicitly accounting for any form of response style heterogeneity as opposed to ERS specifically.

Finally, it is naturally also possible to address ERS bias by simply collapsing score categories (e.g., converting 7-point Likert responses into agree/neutral/disagree) so as to remove information from the item scores regarding extremity. While such an approach would remove effects related to ERS, it comes at the expense of reducing potential meaningful variance among respondents as well as items (Baumgartner and Steenkamp, 2001).

Future Directions

There remain many directions for future work in relation to ERS. One important issue relates to how best to design survey instruments so as to limit the effects of ERS. In particular, survey design issues that consider both (1) how to minimize the occurrence of ERS (e.g., through item writing and/or features of rating scales) and (2) how to make it reliably assessed at the respondent level when present (e.g., through including items of widely varying difficulty levels) remain important issues. Further applications of anchoring vignette strategies and related techniques will be important in evaluating the potential value of this methodology and the plausibility of its assumptions. Other techniques that can be adopted so as to generate more consistency in rating scale usage across respondents would also be worth exploring.

A second issue relates to further study of statistical models and their relative effectiveness in addressing problems introduced by ERS. In particular, attempts to compare methods such as the scale heterogeneity model that account for all forms of rating scale heterogeneity against models that address only response style types such as ERS will be useful.

Finally, one large challenge in synthesizing research on ERS relates not only to the diversity of statistical methods applied in measuring and controlling for its effects, but also to the widely varying conditions associated with the different survey administration contexts in which it is studied. It seems clear from past research that there are likely many different reasons respondents engage in ERS behavior, many of which will be more prominent in some settings than in others. It is likely that progress in this area of research will need to deal more explicitly with this diversity, and that final recommendations for how to address ERS may well need to be closely linked to the context of measurement.

Surveys: Question Wording and Response Categories

Abstract

A large literature provides the basis for recommendations about how to improve the reliability and validity of standardized measurement, whether in survey interviews or in other contexts. Building on an analysis of question characteristics and the decisions required when writing questions, this article summarizes implications of relevant research. We present illustrations of revisions that apply guidelines for improving question.

Introduction

Writing questions for standardized survey measurement requires attention to how survey constructs are conceptualized and operationalized as well as to the technical issues that arise in composing the items themselves. Questionnaire designers are increasingly focusing on the characteristics of questions to better understand how they affect measurement and nonresponse error (e.g., Alwin, 2007; Willis, 2005). Based on an extensive review of the characteristics of survey questions (Schaeffer and Dykema, 2011), the authors proposed that question writers and researchers consider the following classes of characteristics: question topic, question type, response dimension, conceptualization and operationalization of the target object, question structure, question form, response categories, question wording, and implementation. Although only a subset of characteristics are discussed here, they all have implications for decisions that question writers have to make, decisions that may affect the response task faced by respondents and therefore the reliability and validity of the resulting data. These technical issues, on which this article focuses, involve a series of related decisions. Our orientation leads us to consider how characteristics of questions are related to each other. For example, a 'middle category' means something different for a bipolar versus a unipolar rating scale. Details of the literature on which this discussion and recommendations are based can be found in recent reviews including Krosnick and Presser (2010), Schaeffer and Dykema (2011), and Schaeffer and Presser (2003).

To be practical, questions must ask for information that respondents are willing and able to provide (see Fowler and Cosenza, 2008). To meet the requirements of measurement, all respondents must understand the question in the way intended by the question writer. Ideally, we would evaluate survey questions based on whether they obtain reliable (low random error and low interviewer variance) and valid (measure the intended concept without systematic error) data. Because studies of reliability and validity are expensive, decisions are often based on surrogate assessments that are plausibly related to these criteria, including cognitive interviews and response patterns such as straight-lining. For example, question characteristics that appear to facilitate cognitive processing by improving comprehension or retrieval are presumed to improve measurement. Additionally, in interviewer-administered surveys, interviewers must be able to read questions accurately (Schaeffer et al., 2010). For example, question characteristics that increase the frequency with which interviewers follow-up are presumed to reduce data quality (Mangione et al., 1992; Schaeffer and Dykema, 2004).

Parts of a Survey Question

We use a fictitious survey question to introduce some basic vocabulary:

> I am going to read you a list of household tasks. (HAND CARD.) For each task, I'd like you to use the categories on this card and tell me if you find the task not at all boring, a little boring, somewhat boring, very boring, or extremely boring.
>
> The first task is vacuuming. How boring you find vacuuming - not at all boring, a little boring, somewhat boring, very boring, or extremely boring?
>
> And how boring do you find mopping floors – not at all boring…

The *preamble* to this question includes an announcement of the *class of events or objects* to be asked about ('household tasks'), *task instructions* (an announcement about how the question is structured and request for the respondent to rate the events on the response dimension 'how boring'), an announcement of the *response dimension* ('how boring'), and a listing of the exact *response categories* ('not at all boring, a little boring, somewhat boring, very boring, extremely boring'). The *structure of the task* is then reinforced by using a *transitional phrase*, "The first task is…" to introduce the first *target object*, that is, the object to be rated ('vacuuming'), which is then followed by the *target question* – the question that requires the respondent's answer ("How boring do you find vacuuming…") – and a repetition of the *response categories*. The part of the target question that is (sometimes optionally) repeated for a set of items (in this case, "How boring do you find…") is commonly called the *question stem*, but we use the label *repeated part* to distinguish it from the *changing part*; in this case, the changing part is a set of objects, that is, specific household tasks, but it may also be a set of statements that the respondent is asked to evaluate. Alwin (2007: pp. 167–172)

describes a set of questions that share common response categories, as these do, as a *battery* and questions that are not a battery but share a common topic as a *series*.

Overview of Question Characteristics

Question Topic, Question Type, and Response Dimension

Question topic can be analyzed at different levels, although surveys are so varied that there is yet no comprehensive analysis that covers both broad and specific aspects of topic (but see Alwin, 2007; Saris and Gallhofer, 2007; Turner and Martin, 1984). We use *question type* to refer to groups of survey questions that require similar decisions or have a similar structure, for example, because they share possible response dimensions. We focus on two important types of questions: questions about events and behaviors and questions that ask for evaluations or judgments using rating scales. (We do not consider other common types of survey questions such as social characteristics, open nominal choice questions (Schuman and Presser, 1981), or rankings (Alwin and Krosnick, 1985).) **Figures 1** and **2**, respectively, summarize decisions that are made for each type of question. Questions about events and behaviors (henceforth 'events') ask about target objects that have occurred in real time because of the actions of self (behaviors) or others (events). The events may be internal (such as a headache) or external (such as being laid off or going to the doctor). Questions about evaluations or judgments (henceforth 'evaluations') require that respondents evaluate a target object (such as 'my job') using an evaluative response dimension (such as 'how satisfied'). We use 'evaluation' to describe this type of question in order to describe the task we ask the respondent to perform. Evaluations may be absolute or comparative, and they are often used as measures of attitudes.

A *response dimension* is the dimension that the question asks the respondent to think about in constructing an answer. As **Figure 1** suggests, questions about events or behaviors can ask about whichever of the response dimensions of occurrence, frequency, duration, rate of occurrence, or date or timing are relevant. For example, for a question about doctor visits, researchers might ask about whether or not the respondent went to the doctor in the past year (occurrence), how many times the respondent saw a doctor (frequency), how long most visits lasted (duration), at what interval they occurred (rate), and when the last visit occurred (date).

Figure 2 summarizes decisions that are made for evaluations that use rating scales. For these questions, the label for the response dimension is chosen based on the research question, and it is usually conceptualized as an ordered or intensity rating task. For rating scales, several technical decisions need to be made about the response dimension: whether to structure the response dimension as unipolar (from low to high) or bipolar (from high negative to high positive), how to orient the response dimension (e.g., beginning with the positive or negative end), how many response categories to include, whether and how to label the response categories, and how to present the response categories (e.g., in self-administered modes, categories can be laid out horizontally or vertically).

Figure 1 Simplified schematic of decisions for questions about events and behaviors Reprinted from Schaeffer, N.C., Dykema, J., 2011. Questions for surveys: current trends and future directions. Public Opinion Quarterly 75 (5), 909–961.

Figure 2 Simplified schematic of decisions for questions that use rating scales Reprinted from Schaeffer, N.C., Dykema, J., 2011. Questions for surveys: current trends and future directions. Public Opinion Quarterly 75 (5), 909–961.

Different types of questions (e.g., events or evaluations) are associated with different topics and different response dimensions. As a result, they are associated with different question structures and question forms (discussed below) and resulting differences in response processes and response errors. Various common response dimensions (e.g., occurrence, frequency, agree/disagree, intensity of a feeling) might be considered a further specification of the type of question. For example, recent work suggests that a type of question in which an object (such as 'vacuuming') is evaluated directly using a response scale built around an appropriate response dimension ('how boring') can be expected to have higher reliability and validity than a similar indirect question in which respondents are asked to rate how much they agree or disagree with a statement about the object (e.g., "How strongly do you agree or disagree that vacuuming is extremely boring?") (Saris et al., 2010; also Dykema et al., 2012; Fowler and Cosenza, 2008; Krosnick and Presser, 2010).

Conceptualization and Operationalization of the Target Object

Most survey questions are written about target objects – events, objects being rated, policy positions, and so on. The *conceptualization and operationalization of the target object* involve important decisions about how to label the target object and the response dimension. For example, in writing a question about the frequency of visits to the doctor in the past year, the question could refer to 'doctor,' 'medical doctor,' or 'health care provider.'

The operationalization of the concept and the resulting wording of the question can be further complicated by conditions, usually using conjunctions, prepositional phrases, subordinate clauses, or modifiers (e.g., "Last week, did you do ANY work for either pay or profit?"); by instructions to include or exclude (Redline, 2013); by examples, such as pictures in a web survey (Couper, 2008); or by other explicit definitions.

The operationalization of the target object in a series of questions may include a type of decomposition. One approach is to decompose a class of objects (e.g., contacts with your doctor), into subclasses (e.g., face-to-face, telephone, email, webchat, electronic chart system). Asking about each subclass separately implements a definition of what constitutes a 'contact with your doctor' in the structure of the questions themselves as an alternative to reading a complex definition. The occurrence of each subclass of contact can be asked about separately using a 'check-all-that-apply' question, a yes/no 'checklist,' or stand-alone questions; or a frequency can be obtained for each type of contact, that is, each subclass. In selecting among the approaches to measure occurrence, the researcher would rely on the small body of research comparing checklist to check-all response formats (see discussion in Schaeffer and Dykema, 2011). If frequencies are obtained for the subclasses, research would predict that the sum of the reports for the subclasses would be larger than the number that would be obtained by simply asking for a total (Belli et al., 2000).

Question Structure

As illustrated by the discussion about decomposition above, decisions about *question structure* concern the relationship between questions (e.g., Dykema and Schaeffer, 2000). Researchers must often decide between using a single question or two closely related questions, and in these cases, 'structure' and 'form' are extremely closely related. Examples include whether or not to use an occurrence filter followed by a frequency question versus a frequency question alone (Schaeffer and Dykema, 1994) or how to group multiple occurrences of a filter and follow-up question (Kreuter et al., 2011).

A decision for some topics is whether to precede a rating scale with a 'no opinion filter' (or another relevant 'don't know' option). The results from such filtered questions can be

compared to those obtained with unfiltered questions, which may or may not offer a 'no opinion' or 'don't know' category or record the answer only if volunteered (Krosnick and Presser, 2010). There is no evidence that using such a filter or offering such a category increases reliability, and using them complicates analysis. Similarly, although there is not much research about this question structure, for a unipolar evaluative response dimension, using a presence/absence filter (e.g., "Are you concerned about food safety?") and an intensity follow-up question appears less desirable than asking the rating question without the filter (Sterngold et al., 1994; review in Schaeffer and Dykema, 2011). In contrast, implementing a bipolar response dimension by asking about valence followed by an intensity question (with three categories) as in 'unfolding' (Malhotra et al., 2009; review in Krosnick and Presser, 2010) appears to increase reliability.

Question Form

Decisions about *question form* involve selecting a format to obtain the desired information. In some cases, there are alternative forms for obtaining the same or similar information, although the resulting data may have different properties. For example, to determine which of a set of objects the respondent might choose (e.g., as the most important problem facing the country), one could present candidate choices and ask the respondent to choose one, use an open question that provided categories for the interviewer to 'field code' the answer into, or simply record the answer to the open question verbatim (e.g., Schuman and Presser, 1981). The following list illustrates some common question forms that are used in standardized interviews:

1. Closed – selection from a set of ordered categories
   a. Ratings
      – (Direct) rating scales
      – (Indirect) statement + categories (e.g., agree/disagree)
   b. Frequencies
      – Grouped frequency categories
      – Rate-based frequency categories
      – Relative frequency categories
2. Closed – choose category or object
   a. Classification questions (e.g., "Are you currently married…?")
   b. Choose one or nominal choice (e.g., "What is the most important problem facing the country these days?")
   c. Choose all that apply
3. Rankings
4. Yes/No
5. Discrete value
   a. Numerical values of various sorts (e.g., dates, age, amounts, times)
   b. Questions that require calculations (e.g., number of eggs eaten in a typical week, percentages)
6. Open
   a. (Record answer verbatim and) interviewer field codes answer in a set of provided categories
   b. Record answer verbatim for coding later

Response Categories

As Figures 1 and 2 suggest, the decisions about response categories for questions about events are different from those for rating scales. As a result, there are dependencies among question characteristics, and they could interact in their effects on reliability and validity (e.g., Alwin, 2007). Consequently, there is some uncertainty in generalizing from studies that do not take the relationship among these question characteristics into account. Analyses of nonexperimental data (e.g., Alwin, 2007) are further limited both by researchers' analysis of the relationship among item characteristics and by the distribution of item characteristics in the set of available items (e.g., the net impact of polarity in rating scales can be investigated only if there is a sufficient number of unipolar and bipolar items in relevant combinations of other characteristics). Thus, for rating scales, results of these studies are potentially affected by whether the response dimension is unipolar or bipolar; for frequency questions, grouped frequency categories (e.g., '1–10 times') and relative frequency categories (i.e., labeled with adverbial phrases such as 'very often') are difficult to compare. The mode of administration and implementation of the items can also affect how categories are interpreted and used by respondents, and so these should, ideally, be controlled as well. Understanding the impact of the way the item is implemented is increasingly important in mixed-mode survey designs, for which researchers want measurement to be comparable across different implementations.

Studies about the number or labeling of frequency categories are fewer than those about rating scales. Some studies compare questions that ask for discrete values (which obtain absolute frequencies) and grouped frequency questions (sometimes called open and closed questions) or different sets of grouped frequency categories (review in Schaeffer and Presser, 2003). For questions that use relative frequency categories, the issues are probably similar to those for unipolar rating scales, although we do not know of any direct comparisons between grouped frequencies and relative frequencies. Taken together, relevant studies have led to a common recommendation to use discrete value rather than grouped frequency or relative frequency categories for frequency questions (e.g., Schaeffer and Presser, 2003), unless there is a specific reason to do otherwise. Asking the respondent to report a number eliminates decisions about the number of and labels for response categories.

For rating scales, there is considerable research about the effect of the number and labeling of response categories. There is substantial evidence from a wide range of experimental and nonexperimental studies across modes that verbal category labels increase reliability, presumably because they are interpreted more consistently than unlabeled numbers (review in Krosnick and Presser, 2010). The choice of labels can be informed by studies that scale adverbial phrases and intensifiers (see Cliff, 1959; Dobson and Mothersill, 1979 for examples). Cliff's (1959) results suggest that the following six categories would be approximately equidistant for a unipolar rating scale: *not at all, slightly, somewhat, quite, very, extremely* (Schaeffer and Presser, 2003). With only five categories, it is more difficult to select labels that have roughly equidistant

scale values. The labels in the fictitious item we gave earlier were chosen for five categories using Cliff (1959). Using Dobson and Mothersill (1979), one might suggest *not at all, slightly, somewhat (or moderately), very, extremely*. All these sets of labels end in 'extremely,' because these studies strongly suggest that 'very' is simply not intense enough to be the highest category for most purposes (see Schaeffer and Presser, 2003).

The choice of the number of categories for a rating scale requires balancing the researcher's desire to make distinctions, the respondent's ability to discriminate, and the capacity of language to supply sensible labels. It is difficult to summarize the evidence about the number of categories for rating scales, for the reasons given in the introduction to this section. Five to seven categories is a common recommendation (Krosnick and Presser, 2010; Schaeffer and Presser, 2003). Often the choice depends on mode: five or fewer is more common in telephone surveys, and there may not be room for seven categories on a paper self-administered instrument. In a mixed-mode study, researchers are likely to consider the most constrained mode. The polarity of the scale may also be a consideration: five categories offer little discrimination on either side of the midpoint, but unfolding makes it possible to increase the number of categories in the final scale by asking valence and then intensity (e.g., with three categories) on the side the respondent chooses (Malhotra et al., 2009; review in Krosnick and Presser, 2010). For a bipolar scale that is not unfolded, there is experimental evidence (using five-category agree–disagree items) that including a labeled midpoint reduced random error without affecting validity (review in Krosnick and Presser, 2010).

Question Wording

There are additional matters of *question wording*. In addition to definitions and task instructions, the preamble or introduction for a question can reinforce reference periods (e.g., "By 'last week' I mean the 7 days beginning Monday March 1st and ending yesterday"), motivate (e.g., "This information is important, so please take your time"), attempt to desensitize (e.g., "In talking to people about elections, we often find a lot of people were not able to vote because they weren't registered, they were sick, or they just didn't have time…"), or improve recall (e.g., Cannell et al., 1981).

Finally, a substantial group of item characteristics concerns language, particularly usage that affects comprehension (e.g., because the vocabulary or grammar is complex) or retrieval (e.g., because the question provides cues or time for retrieval) (Tourangeau et al., 2000). These include question length; reading difficulty of the vocabulary; number of words that are vague, ambiguous, or technical; and grammatical complexity (e.g., number of clauses, number of conjunctions) (Graesser et al., 2006).

Guidelines for Writing Survey Questions

Technical guidelines for writing questions draw on research examining implementation (e.g., ease of processing and respondents' preferences) and the consequences for measurement (e.g., validity, reliability) of various question characteristics. The literature cited earlier offers guidelines about various aspects of question writing. We offer a few examples here. The revised questions in these illustrations are not intended to model all 'best practices,' but only to show a revision of the problem under discussion.

For example, with regard to decisions that have to be made about vocabulary and word choice, question writers are advised to use native vocabulary in place of analytic vocabulary in order to improve both comprehension and retrieval. The analytic vocabulary used by the analyst includes construct labels, technical terms, and jargon. Native vocabulary, the language used by the respondent, can be uncovered in developmental and cognitive interviews (Schaeffer and Dykema, 2004). Aids such as QUAID (Question Understanding AID) (Graesser et al., 2006) can be helpful in identifying technical and unfamiliar words. The examples below illustrate how technical vocabulary can be simplified:

Analytic vocabulary	*Revision*	*Source*
Occupants of this household	People who live here	Dillman et al. (2009)
Your responses	Your answers	Dillman et al. (2009)

Other technical guidelines are about the relationship between question structure and the response categories. For example, question writers are advised to match the format provided by the response categories to those requested by or projected by the question. Often, survey questions are written so that the question requests an answer in a format different from that provided. In Problematic Question 1 below, the response categories require the interviewer to enter the month and year. The question is less specific, asking only 'when' the respondent last saw his child, a question that could elicit a variety of responses only some of which will be a month and year. As already noted, if the interviewer has to probe for a codable response, interviewer variability and random error increase. The revised question clearly projects the categories in which the response is desired (see Fowler and Cosenza, 2008).

Problematic question 1

When did you last see CHILD?
MO _____ YR _____

Revision

In what month and year did you last see CHILD?
MO _____ YR _____

Similarly, the response dimension in the question should match the response categories in the question. In Problematic Question 2, the response dimension implied by the question, 'occurrence' (i.e., 'did you feel'), does not match the response dimension reflected in the response categories, 'frequency expressed as a rate' (i.e., 'never, about once a month, about once a week, or more often than once a week'). The response

dimension in the question and the response categories match in the revision.

Problematic question 2

During the last 12 months, did you feel like you just didn't know where the next day's food was going to come from? Never, about once a month, about once a week, or more often than once a week?

Revision

During the last 12 months, how often did you feel like you just didn't know where the next day's food was going to come from? Never, about once a month, about once a week, or more often than once a week?

In Problematic Question 3, the response dimension in the question (i.e., 'how often') does not match the response dimension in the response categories, frequency expressed as a number of times.

Problematic question 3

How often did you see CHILD last month?
ENTER NUMBER OF TIMES _____

Revision

How many times did you see CHILD last month?
ENTER NUMBER OF TIMES _____

In Problematic Question 4, the response dimension in the question, occurrence, does not match the response dimension in the response categories (i.e., 'often true, sometimes true, never true'). In Revision (1), the question is rewritten to ask about occurrence; in Revision (2), the question is rewritten to ask for relative frequencies; and in Revision (3), the question is rewritten to ask for absolute frequencies.

Problematic question 4

"I worried about whether my food would run out before I got money to buy more." Was that often true, sometimes true, or never true for you in the last 12 months?

Revision 1

In the last 12 months, did you worry about whether your food would run out before you got money to buy more?
YES
NO

Revision 2

In the last 12 months, how often did you worry about whether your food would run out before you got money to buy more? Often, sometimes, or never?

Revision 3

In the last 12 months, on how many days did you worry about whether your food would run out before you got money to buy more?
____ NUMBER OF DAYS

Conclusion

In this article, we have provided an overview of several classes of question characteristics and described some of their effects on measurement. The usefulness of research about survey questions depends, ultimately, on the underlying analysis of the characteristics of questions, which characteristics are compared, and how the dependencies among question characteristics are taken into account in the study design. For example, what characteristics of questions should be held constant when the effect of another characteristic is being estimated? Making progress in understanding how the characteristics of questions affect measurement requires that we also develop our understanding of what those characteristics are and how they covary or nest within each other. Additional topics, such as how the structure of the entire instrument or mode in which the instrument is administered affect data quality, also need exploration with stronger research designs.

Survival Analysis: Introduction

Niels Keiding and Per K Andersen, University of Copenhagen, Copenhagen K, Denmark

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Survival analysis is the study of the distribution of time-to-event data, that is, the times from an initiating event to some terminal event. A distinguishing feature of survival data is the occurrence of right censoring, where the terminal event for some individuals is not observed; instead, it is only known that this event is at least later than a given point in time.

This article presents a brief historical review and focuses on central statistical approaches: non- and semiparametric estimation (Kaplan–Meier, Cox regression) and hypothesis testing (log-rank). We also add brief comments on parametric models and list some important reference works.

Introduction

Survival analysis is the study of the distribution of time-to-event data, that is, the times from an initiating event (birth, start of treatment, employment in a given job) to some terminal event (death, relapse, disability pension). A distinguishing feature of survival data is the inevitable presence of incomplete observations, particularly when the terminal event for some individuals is not observed; instead, it is only known that this event is at least later than a given point in time: *right censoring*.

History

Survival analysis is one of the oldest statistical disciplines with roots in demography and actuarial science in the seventeenth century; see Westergaard (1901: Chapter 2; 1932) for general accounts of vital statistics and Hald (1990) for specific accounts of the work before 1750. More specifically, competing risks had been studied since at least 1760 by Bernoulli (see Seal, 1977 and Dietz and Heesterbeek, 2002), indirect and direct standardization since at least 1777 (Keiding, 1987; Keiding and Clayton, to appear), and the simultaneous handling of age, period, and cohort since the 1870s (Lexis, 1875; cf Keiding, 2011).

In the midtwentieth century the above techniques were well established, usually formalized in discrete time with consequent necessary approximations when describing the inherently continuous underlying time. The penetrating study by Kaplan and Meier (1958), the fascinating genesis of which was chronicled by Breslow (1991), eliminated in principle the need for these approximations in the situations where all survival and censoring times are known precisely. Following Böhmer (1912), Kaplan and Meier shrank the observation interval to include at most one observation per interval. Though overlooked by many later authors, Kaplan and Meier also formalized the age-old handling of delayed entry – again, see also Böhmer (1912) – through the necessary adjustment for the risk set, the set of individuals alive and under observation at a particular value of the relevant time variable.

Other remarkable contributions from the midtwentieth century include the pioneering study by Harris et al. (1950) on what is now termed interval-censored survival data, where each event is only known to have occurred in a time interval, usually different for each individual, and the combination by Ederer et al. (1961) of the old calculation of expected number of deaths with survival distribution estimation into the relative survival rate.

Nonparametric Estimation and Testing

The simplest situation encountered in survival analysis is the nonparametric estimation of a survival distribution function based on a right-censored sample of observation times $(\widetilde{X}_1, \ldots, \widetilde{X}_n)$. Here, each $\widetilde{X}_i$ is either a survival time X_i, in which case the failure/censoring indicator D_i takes the value 1, or it is a right-censoring time, say U_i, and then $D_i = 0$. The true survival times X_i, $i = 1, \ldots, n$, are assumed to be independent and identically distributed with common survival distribution function $S(t) = P(T_i > t)$, whereas as few assumptions as possible are usually made about the right-censoring times U_i except for the assumption of *independent censoring*, see Andersen et al. (1993: Section III.2.2) or Kalbfleisch and Prentice (2002: p. 195). The concept of independent censoring has the interpretation that the fact that an individual, i, is alive *and uncensored* at time t, say, should not provide more information on the survival time for that individual than $X_i > t$, i.e., the right-censoring mechanism should not remove individuals from the study who are at a particularly high or a particularly low risk of dying. Under these assumptions, $S(t)$ is estimated by the *Kaplan–Meier estimator* (Kaplan and Meier, 1958). This is given by

$$\widehat{S}(t) = \prod_{\widetilde{X}_i \le t} \left[1 - D_i / Y(\widetilde{X}_i)\right] \qquad [1]$$

where $Y(t) = \sum I(\widetilde{X}_i \ge t)$ is the number of individuals *at risk* just before time t. The Kaplan–Meier estimator is a nonparametric maximum likelihood estimator (Kaplan and Meier, 1958; Johansen, 1978; Andersen et al., 1993: Section IV.3.1) and its asymptotic properties as $n \to \infty$ are very well studied since Breslow and Crowley (1974), see Andersen et al. (1993: Chapter IV).

Thus, in large samples, $\widehat{S}(t)$ is approximately normally distributed with mean $S(t)$ and a variance which may be estimated by Greenwood's (1926) formula:

$$\widehat{\sigma}^2(t) = \left[\widehat{S}(t)\right]^2 \sum_{\widetilde{X}_i \le t} \frac{D_i}{Y(\widetilde{X}_i)\left[Y(\widetilde{X}_i) - 1\right]} \qquad [2]$$

From this result, point-wise confidence intervals for $S(t)$ are easily constructed and, since one can also show weak convergence of the entire Kaplan–Meier curve $\{\sqrt{n}[\widehat{S}(t) - S(t)]; 0 \le t \le \tau\}, \tau \le \infty$ to a mean zero Gaussian process, simultaneous confidence bands for $S(t)$ on $[0, \tau]$ can also be set up, see, e.g., Andersen et al. (1993, Section IV.3.3) for details.

As an alternative to describing the distribution of survival times via the survival function $S(t)$, the *hazard function* $\alpha(t) = -S'(t)/S(t)$, or the *cumulative hazard function* $A(t) = -\log S(t)$ may be applied. Thus, the latter may be estimated by the *Nelson–Aalen estimator*,

$$\widehat{A}(t) = \sum_{\widetilde{X}_i \le t} D_i / Y(\widetilde{X}_i) \qquad [3]$$

(Nelson, 1969; Aalen, 1978; see also Andersen et al., 1993: Section IV.1). The relation between the estimators $\widehat{S}(t)$ and $\widehat{A}(t)$ is given by the *product integral* (Gill and Johansen, 1990) from which it follows that their large sample properties are equivalent. Though the Kaplan–Meier estimator has the advantage that a survival *probability* is easier to interpret than a cumulative hazard function, the Nelson–Aalen estimator is easier to generalize to multistate situations beyond the survival data context (*see* Event History Analysis in Continuous Time). To give a nonparametric estimate of the hazard function $\alpha(t)$ itself requires some smoothing techniques to be applied.

Right censoring is not the only kind of data-incompleteness to be dealt with in survival analysis; in particular, individuals may not all be followed from time 0 but may be from a later entry time V_i conditionally on having survived until V_i, so-called *left truncation* or *delayed entry*. Dealing with left truncation only requires a redefinition of the *risk set* from the set $\{i : \widetilde{X}_i \ge t\}$ of individuals still alive and uncensored at time t to the set $\{i : V_i < t \le \widetilde{X}_i\}$ of individuals with entry time $V_i < t$ and who are still alive and uncensored. With $Y(t)$ still denoting the size of the risk set at time t, eqns [1], [2], and [3] are applicable though one should be aware of the fact that estimates of $S(t)$ and $A(t)$ may be ill-determined for small values of t due to the left-truncation.

When the survival time distributions in a number, k, of homogeneous groups have been estimated nonparametrically it is often of interest to test the hypothesis H_0 of identical hazards in all groups. Thus, based on censored survival data $[(\widetilde{X}_{hi}, D_{hi}), i = 1, \ldots, n_h]$ for group h, $h = 1 \ldots k$, the Nelson–Aalen estimates $\widehat{A}_h(t)$ may be computed, and based on the combined sample of size $n = \sum_h n_h$ with data $[(\widetilde{X}_i, D_i), i = 1, \ldots, n]$ an estimate of the common cumulative hazard function $A(t)$ under H_0 may be obtained by a Nelson–Aalen estimator $\widehat{A}(t)$. As a general statistic for testing H_0, one may then use a k-vector of sums of weighted differences between the increments of $\widehat{A}_h(t)$ and $\widehat{A}(t)$ (Aalen, 1978; Andersen et al., 1982):

$$Z_h = \sum_{i=1}^{n} K_h(\widetilde{X}_i)\left[\Delta\widehat{A}_h(\widetilde{X}_i) - \Delta\widehat{A}(\widetilde{X}_i)\right] \qquad [4]$$

Here, $\Delta\widehat{A}_h(t) = 0$ if t is not among the observed survival times in the hth sample and $K_h(t)$ is 0 whenever $Y_h(t) = 0$, in fact all weight functions used in practice have the form $K_h(t) = Y_h(t) K(t)$. With this structure for the weight function, the covariance between Z_h and Z_j given by eqn [4] is estimated by

$$\sigma_{hj} = \sum_{i=1}^{n} K^2(\widetilde{X}_i) \frac{Y_h(\widetilde{X}_i)}{Y(\widetilde{X}_i)} \left[\delta_{hj} - \frac{Y_j(\widetilde{X}_i)}{Y(\widetilde{X}_i)}\right] D_i \qquad [5]$$

and, letting Z be the k-vector $(Z_1, \ldots, Z_k)'$ and $\sum$ the k by k matrix $(\sigma_{hj}, h, j = 1, \ldots, k)$ the test statistic $X^2 = Z' \sum^- Z$ is asymptotically chi-squared distributed under H_0 with $k-1$ degrees of freedom if all n_h tend to be infinity at the same rate, cf Andersen et al. (1993: Section V.2). Here, $\sum^-$ is a generalized inverse for $\sum$.

Special choices for $K(t)$ correspond to test statistics with different properties for particular alternatives to H_0. An important such test statistic is the *log-rank* test (Peto and Peto, 1972) obtained for $K(t) = I[Y(t) > 0]$. For this test, which has particularly good power for *proportional hazards* alternatives, Z_h given by eqn [4] reduces to $Z_h = O_h - E_h$ with O_h the total number of observed failures in group h and $E_h = \sum D_i Y_h(\widetilde{X}_i)/Y(\widetilde{X}_i)$ an 'expected' number of failures in group h. For the two-sample case ($k = 2$), one may of course use the square root of X^2 as an asymptotically normal test statistic for the null hypothesis. For the case where the k groups are *ordered*, and where a *score* x_h (with $x_1 \le \ldots \le x_k$) is attached to group h, a *test for trend* is given by $T^2 = (x'Z)^2/x' \sum x$ with $x = (x_1, \ldots, x_k)'$ and it is asymptotically chi-squared with 1 df, cf Andersen et al. (1993: Section V.3.3).

The above linear rank tests have low power against certain important classes of alternatives such as 'crossing hazards.' Just as for uncensored data, this has motivated the development of test statistics of the Kolmogorov–Smirnov and Cramèr–von Mises types, based on maximal deviation or integrated squared deviation between estimated hazards, cumulative hazards, or survival functions, cf Andersen et al. (1993: Section V.4.1).

Parametric Inference

The nonparametric methods outlined in the previous section have become the standard approach to the analysis of simple homogeneous survival data without covariate information. However, parametric survival time distributions are sometimes used for inference, and we shall here give a brief review. Assume again that the true survival times $X_1, \ldots, X_n$ are independent and identically distributed with survival distribution function $S(t; \theta)$ and hazard function $\alpha(t; \theta)$ but that only a right-censored sample $(\widetilde{X}_i, D_i), i = 1, \ldots, n$, is observed. Under independent censoring the likelihood function for the parameter θ is

$$L(\theta) = \prod_{i=1}^{n} \left[\alpha(\widetilde{X}_i; \theta)\right]^{D_i} S(\widetilde{X}_i; \theta) \qquad [6]$$

The function of eqn [6] may be analyzed using standard large sample theory, see e.g., Andersen et al. (1993: Chapter VI). Thus, standard tests, i.e., Wald-, score-, and likelihood ratio

tests are used as inferential tools. Two frequently used parametric survival models are the *Weibull* distribution with hazard function $\alpha\rho(\alpha t)^{\rho-1}$, and the piecewise exponential distribution with $\alpha(t, \theta) = \alpha_j$ for $t \in I_j$ with $I_j = [t_{j-1}, t_j)$, $0 = t_0 < t_j < \ldots < t_m = \infty$. Both of these distributions contain the very simplest model, the exponential distribution with a constant hazard function, as null cases.

Comparison with Expected Survival

As a special case of the nonparametric tests discussed above, a *one-sample* situation may be studied. This may be relevant if one wants to compare the observed survival in the sample with the *expected survival* based on a standard life table. Thus, assume that a hazard function $\alpha^*(t)$ is given and that the hypothesis H_0: $\alpha = \alpha^*$ is to be tested. One test statistic for H_0 is the one-sample *log-rank test* $(O - E^*)/(E^*)^{1/2}$ where E^*, the 'expected' number of deaths is given by $E^* = \sum[A^*(\widetilde{X}_i) - A^*(V_i)]$ (with A^* the cumulative hazard corresponding to α^*). In this case $\widehat{\theta} = O/E^*$, the *standardized mortality ratio*, is the maximum likelihood estimate for the parameter θ in the model $\alpha(t) = \theta\alpha^*(t)$ (Kilpatrick, 1962; Breslow, 1975; Keiding, 1987; Nielsen, 1997; Keiding and Clayton, to appear). Thus, the standardized mortality ratio arises from a *multiplicative* model involving the known population hazard $\alpha^*(t)$. Another classical tool for comparing with expected survival, the so-called *expected survival function*, arises from an *additive or excess* hazard model (Andersen and Væth, 1989).

The Cox Regression Model

In many applications of survival analysis the interest focuses on how *covariates* may affect the outcome; in clinical trials adjustment of treatment effects for effects of other explanatory variables may be crucial if the randomized groups are unbalanced with respect to important prognostic factors, and in epidemiological cohort studies reliable effects of exposure may be obtained only if some adjustment is made for confounding variables. In these situations, a *regression model* is useful and the most important model for survival data is the Cox (1972) *proportional hazards regression model*. (See Prentice (1991) and Reid (1994) for descriptions of the genesis of the Cox model.) In its simplest form it states the hazard function for an individual, i, with covariates $Z_i = (Z_{i1}, \ldots, Z_{ip})'$ to be

$$\alpha_i(t; Z_i) = \alpha_0(t)\exp(\beta' Z_i) \qquad [7]$$

where $\beta = (\beta_1, \ldots, \beta_p)'$ is a vector of unknown regression coefficients and $\alpha_0(t)$, the *baseline hazard*, is the hazard function for individuals with all covariates equal to 0. Thus, the baseline hazard describes the common shape of the survival time distributions for all individuals while the *relative risk* function $\exp(\beta' Z_i)$ gives the level of each individual's hazard. The interpretation of the parameter, β_j for a dichotomous $Z_{ij} \in \{0,1\}$ is that $\exp(\beta_j)$ is the hazard ratio for individuals with $Z_{ij} = 1$ compared to those with $Z_{ij} = 0$, all other covariates being the same for the two individuals. Similar interpretations hold for parameters corresponding to covariates taking more than two values.

The model is *semiparametric* in the sense that the relative risk part is modeled parametrically while the baseline hazard is left unspecified. The regression coefficients β are estimated by maximizing the Cox (1975) *partial likelihood*

$$L(\beta) = \prod_{i=1}^{n} \left[\frac{\exp(\beta' Z_i)}{\sum_{j \in R_i} \exp(\beta' Z_j)} \right]^{D_i} \qquad [8]$$

where $R_i = \{j : \widetilde{X}_j \geq \widetilde{X}_i\}$, the *risk set* at time $\widetilde{X}_i$, is the set of individuals still alive and uncensored at that time. Furthermore, the cumulative baseline hazard $A_0(t)$ is estimated by the *Breslow estimator*

$$\widehat{A}_0(t) = \sum_{\widetilde{X}_i \leq t} D_i / \sum_{j \in R_i} \exp\left(\widehat{\beta}' Z_j\right) \qquad [9]$$

which is the Nelson–Aalen estimator one would use if β were known and equal to the maximum partial likelihood estimate $\widehat{\beta}$. The estimators based on eqns [8] and [9] also have a nonparametric maximum likelihood interpretation. In large samples, $\widehat{\beta}$ is approximately normally distributed with the proper mean and with a covariance, which is estimated by the information matrix based on eqn [8]. This means that approximate confidence intervals for the relative risk parameters of interest can be calculated and that the usual large sample test statistics based on eqn [8] are available. Also, the asymptotic distribution of the Breslow estimator is normal; however, this estimate is most often used as a tool for estimating *survival probabilities* for individuals with given covariates, Z_0. Such an estimate may be obtained by the product integral $\widehat{S}(t; Z_0)$ of $\exp(\widehat{\beta}' Z_0)\widehat{A}_0(t)$. The *joint* asymptotic distribution of $\widehat{\beta}$ and the Breslow estimator then yields an approximate normal distribution for $\widehat{S}(t; Z_0)$ in large samples.

As is the case for many other statistical models for discrete data and survival data, the Cox regression model has no separate variance parameter but estimates the 'noise' from the mean value parameters. However, since Lin and Wei (1989), robust 'sandwich' variance estimates have been available for the Cox model, and these are now included in many software packages. See Keiding (2014) for some general remarks in this connection.

A number of useful extensions of this simple Cox model are available. Thus, in some cases the covariates are *time-dependent*, e.g., a covariate might indicate whether or not a given event had occurred by time t, or a time-dependent covariate might consist of repeated recordings of some measurement likely to affect the prognosis. In such cases the regression coefficients β are estimated replacing $\exp(\beta' Z_j)$ in eqn [8] by $\exp[\beta' Z_j(\widetilde{X}_i)]$.

Also a simple extension of the Breslow estimator eqn [9] applies in this case. However, the survival function can, in general, no longer be estimated in a simple way because of the extra randomness arising from the covariates, which is not modeled in the Cox model. This has the consequence that the estimates are more difficult to interpret when the model contains time-dependent covariates. To estimate the survival function in such cases a joint model for the hazard and the time-dependent covariate may be used. See our article on Event History Analysis in Continuous Time for some further remarks on time-dependent covariates and time-dependent confounding.

Another extension of eqn [7] is the *stratified* Cox model where individuals are grouped into a number, k of strata each of which has a separate baseline hazard. This model has important applications for checking the assumptions of eqn [7]. The model assumption of proportional hazards may also be *tested* in a number of ways, the simplest possibility being to add interaction terms of the form Z_{ij} $f(t)$ between Z_{ij} and time where $f(t)$ is some specified function. Also various forms of *residuals* as for normal linear models may be used for model checking in eqn [7]. A careful review of current methods for goodness-of-fit procedures of the Cox model was given by Martinussen and Scheike (2006).

There are many general reviews of the Cox model; among them we mention Sasieni (2005) and Oakes (2013).

Other Regression Models for Survival Data

Though the semiparametric Cox model is the regression model for survival data, which is applied most frequently, other regression models, e.g., *parametric* regression models also play important roles in practice. Examples include models with a multiplicative structure, i.e., models like eqn [7] but with a parametric specification, $\alpha_0(t) = \alpha_0(t;\ \theta)$, of the baseline hazard, and *accelerated failure time models*.

A multiplicative model with important epidemiological applications is the *Poisson regression* model with a piecewise constant baseline hazard (Breslow and Day, 1987; Clayton and Hills, 1993). In large data sets with categorical covariates this model has the advantage that a sufficiency reduction to the number of failures and the amount of person-time at risk in each *cell* defined by the covariates and the division of time into intervals is possible. This is in contrast to the Cox regression model eqn [7] where each individual data record is needed to compute eqn [8]. The substantial computing time required to maximize eqn [8] in large samples has also led to modifications of this estimation procedure. Thus, in *nested case–control studies* the risk set R_i in the Cox partial likelihood is replaced by a random sample $\widetilde{R}_i$ of R_i (see Borgan et al., 1995).

In the accelerated failure time model the focus is not on the hazard function but on the survival time itself much like in classical linear models. Thus, this model is given by $\log X_i = \alpha + \beta' Z_i + \varepsilon_i$ where the error terms are assumed to be independent and identically distributed with expectation 0. Examples include normally distributed (ε_i, $i = 1 \ldots n$), and error terms with a logistic or an extreme value distribution, the latter giving rise to a regression model with Weibull distributed life times.

Finally, we shall mention some nonparametric hazard models. In Aalen's additive model, $\alpha_i(t) = \beta_0(t) + \beta(t)' Z_i(t)$ (Aalen, 1980; Aalen et al., 2008), the regression functions $\beta_0(t), \ldots, \beta_p(t)$ are left completely unspecified and estimated nonparametrically much like the Nelson–Aalen estimator discussed above. This model provides an attractive alternative to the other regression models discussed in this section. There also exist more general and flexible models containing both this model and the Cox regression model as special cases (Martinussen and Scheike, 2006).

Other Kinds of Incomplete Observation

Salient features of survival data are right censoring and left truncation, and we have referred to them throughout this survey. In some cases only events (such as AIDS cases) that occur *before* a certain time are included (right-truncation).

More generally, event times may only be known to lie in an interval. If these intervals are the same for all individuals one may use the grouped time approach inherent in the Poisson regression model with piecewise constant intensities, or the discrete time approach, see e.g., Fahrmeir and Tutz (2001). If the intervals are not synchronous, more general techniques for interval-censored data (Sun, 2006) become relevant.

Concluding Remarks, Main References

Survival analysis is a well-established discipline in statistical theory, in biostatistics, and with significant presence both in econometrics and social statistics. Important general texts are the documentation of the actuarial and demographical traditions by Elandt-Johnson and Johnson (1980), the comprehensive texts by Kalbfleisch and Prentice (2002) and Lawless (2002) and the concise text by Cox and Oakes (1984). Andersen et al. (1993) covered the counting process approach and gave many details on the methods outlined in the present article; for follow-up texts see Martinussen and Scheike (2006) and Aalen et al. (2008). *The Encyclopedia of Biostatistics* (Second ed., Armitage and Colton, 2005) had many articles on survival analysis, collected in the separate volume edited by Andersen and Keiding (2006). The Bayesian approach was covered by Ibrahim et al. (2001). The recent *Handbook of Survival Analysis* (Klein et al., 2014) provides a fine overview, with some emphasis on biostatistical applications.

Among texts specifically intended for social and behavioral science users we mention the classic by Allison (1984), of which a second edition should be forthcoming in 2014, and texts by Blossfeld and Rohwer (1995), Courgeau and Lelièvre (1992) and Mills (2011).

Abstract

Survival analysis, sometimes referred to as failure-time analysis, refers to the set of statistical methods used to analyze time-to-event data. Time-to-event or failure-time data, and associated covariate data, may be collected under a variety of sampling schemes, and very commonly involves right censoring. The distribution of a failure-time variate is usefully characterized in terms of its conditional failure rate, or hazard, function. Hazard-function modeling integrates nicely with the aforementioned sampling schemes, leading to convenient techniques for statistical testing and estimation. For univariate failure-time data those techniques include Kaplan–Meier estimators of the survivor function, censored data rank tests to compare the survival distributions of two or more groups, and relative risk (Cox) regression procedures for associating the hazard rate with a vector of study subject characteristics. Alternatively, linear models for the logarithm of failure time, for example, may be used for the regression analysis of failure-time data. Multivariate failure times may arise in the form of multiple events of various types on individual study subjects, or in the form of correlated failure times on distinct study subjects. The methods for the analysis of these types of data are still being actively researched. There are many additional specialized methods in survival analysis, including covariate measurement-error procedures, cohort-sampling strategies, and testing and estimation under sequential monitoring, to name just a few.

Failure-Time Data and Representation

The term survival analysis has come to embody the set of statistical techniques used to analyze and interpret time-to-event, or failure-time data. The events under study may be disease occurrences or recurrences in a biomedical setting, machine breakdowns in an industrial context, or the occurrence of major life events in a longitudinal-cohort setting. It is important in applications that the event of interest be defined clearly and unambiguously. A failure-time variable T is defined for an individual as the time from a meaningful origin or starting point, such as date of birth, or date of randomization into a clinical trial, to the occurrence of an event of interest. For convenience, we refer to the event under study as a failure.

A cohort study involves selecting a representative set of individuals from some target population and following those individuals forward in time in order to record the occurrence and timing of the failures. Often, some study subjects will still be without failure at the time of data analysis, in which case their failure times T will be known only to exceed their corresponding censoring times. In this case, the censoring time is defined as the time elapsed from the origin to the latest follow-up time, and the failure time is said to be right censored. Right censorship may also arise because subjects drop out the study, or are lost to follow-up. A key assumption underlying most survival analysis methods is that the probability of censoring an individual at a given follow-up time does not depend on subsequent failure times. This independence assumption implies that individuals who are under study at time t are representative of the cohort and precludes, for example, the censoring of individuals at time t because, among individuals under study at that time, they appear to be at unusually high (or low) risk of failure. (This assumption can be relaxed to independence between censoring and failure times conditional on the preceding histories of covariates.) The reasonableness of the independent censoring assumption, which usually cannot be tested directly, should be considered carefully in specific applications.

The distribution of a failure time variate $T > 0$ is readily represented by its survivor function $F(t) = P(T > t)$. If T is absolutely continuous, its distribution can also be represented by the probability density function $f(t) = -dF(t)/dt$ or by the hazard, or instantaneous failure rate, function defined by.

$$\lambda(t) = \lim_{\Delta t \downarrow 0} P(t \le T < t + \Delta t | T \ge t)/\Delta t = f(t)/F(t^-). \quad [1]$$

Note that

$$F(t) = \exp\{-\int_0^t \lambda(u)\mathrm{d}u\}, \quad \text{and}$$

$$f(t) = \lambda(t)\exp\{-\int_0^t \lambda(u)\mathrm{d}u\}$$

$$\text{for } 0 < t < \infty$$

In a similar way, the distribution of a discrete failure time variate T, taking values on $x_1 < x_2 < \cdots$, can be represented by its survivor function, its probability function$f(x_i) = P(T = x_i), i = 1,2\ldots$, or its hazard function $\lambda(x_i) = P(T = x_i | T \ge x_i) = f(x_i)|F(x_i^-)$. Note that

$$F(t) = P(T > t) = \prod_{i|x_i \le t} [1 - \lambda(x_i)] \quad [2]$$

as arises through thinking about the failure mechanism unfolding sequentially in time. To survive past time t where $x_j \le t < x_{j+1}$, an individual must survive in sequence each of the points $x_1,\ldots, x_j$ with conditional probabilities $1 - \lambda(x_i), i = 1,\ldots, j$.

It is often natural and insightful to focus on the hazard function. For example, human mortality rates are known to be elevated in the first few years of life, to be low and relatively flat

for the next three decades or so, and then to increase rapidly in the later decades of life. Similarly, comparison of hazard rates as a function of time from randomization for a new treatment compared with control can provide valuable insights into the nature of treatment effects. Hazard function modeling also integrates nicely with a number of key strategies for selecting study subjects from a target population. For example, if one is studying disease occurrence as it depends upon the age of study subjects, hazard function models readily accommodate varying ages at entry into the study cohort since the conditioning event in (1) specifies that the individual is surviving and event-free at age t. Again one needs to assume that selected subjects have hazard rates that are representative (conditional on covariates) of those at risk for the target population.

Estimation and Comparison of Survival Curves

Suppose that a cohort of individuals has been identified at a time origin $t = 0$ and followed forward in time. Suppose that failures are observed at times $t_1 < t_2 < \cdots < t_k$. Just prior to the failures observed at time t_j, there will be some number, r_j, of cohort members that are under active follow-up. That is, the failure and censoring times for these r_j members occur at time t_j or later. Of these r_j individuals, some number, d_j, are observed to fail at t_j. The empirical failure rate or estimated hazard at t_j is then d_j/r_j, and the empirical survival rate is $(1 - d_j/r_j)$. The empirical failure rate at all times other than $t_1,\ldots, t_k$ in the follow-up period is zero. The Kaplan and Meier (1958) estimator of the survivor function F at follow-up time t is.

$$\widehat{F}(t) = \prod_{\{t_j \le t\}} (1 - d_j/r_j) \qquad [3]$$

the product of the empirical survivor rates across the observed failure times less than or equal to t. Note that $\widehat{F}$ estimates the underlying survivor function F at those times where there are cohort members at risk. For (3) to be valid, the cohort members at risk at any follow-up time t must have the same failure rate operating as does the target population at that follow-up time. Thus, the aforementioned independent censoring assumptions are needed.

The hazard rate estimators $d_j/r_j, j = 1,\ldots, k$ can be shown to be uncorrelated, giving rise to the Greenwood variance estimator.

$$\mathrm{var}\{\widehat{F}(t)\} = \widehat{F}(t)^2 \sum_{\{t_j \le t\}} d_j/\{r_j(r_j - d_j)\} \qquad [4]$$

for $\widehat{F}(t)$. In-order to show asymptotic results for the estimator $\widehat{F}(t)$, for example that $\widehat{F}(t)$ is a consistent estimator of $F(t)$, it is necessary to restrict the estimation to a follow-up interval $[0, \tau)$ within which the size of the risk set (i.e., number of individuals under active follow-up) becomes large as the sample size (n) increases. Under these conditions, $n^{1/2}\{\widehat{F}(t) - F(t)\};\ 0 \le t < \tau$ can be shown to converge weakly to a mean-zero Gaussian process, permitting the calculation of approximate confidence intervals and bands for F on $[0, \tau)$. Applying the asymptotic results to the estimation of $log\{-log F(t)\}$, which has no range restrictions, is suggested as a way to improve the coverage rates of asymptotic confidence intervals and bands (Kalbfleisch and Prentice, 1980: pp. 14, 15).

Consider a test of equality of m survivor functions $F_1,\ldots, F_m$ on the basis of failure-time data from each of m populations. Let $t_1 < t_2 < \cdots < t_k$ denote the ordered failure times from the pooled data, and again let d_j failures occur out of the r_j individuals at risk just prior to time t_j, $j = 1,\ldots, k$. Also, for each sample $i = 1,\ldots, m$, let d_{ij} denote the number of failures at t_j, and r_{ij} denote the number at risk at t_j^-. Under the null hypothesis $F_1 = F_2 = \cdots = F_m$ the conditional distribution of $d_{1j},\ldots, d_{mj}$ given $(d_j, r_{1j},\ldots, r_{mj})$ is hypergeometric from which the conditional mean and variance of d_{ij} are respectively $u_{ij} = r_{ij}(d_j/r_j)$ and $(V_j)_{ii} = r_{ij}(r_i - r_{ij})d_j(r_j - d_j)r_j^{-2}(r_j - 1)^{-1}$ The conditional covariance of d_{ij} and $d_{\ell j}$ is.

$$(V_j)_{i\ell} = r_{ij}r_{\ell j}d_j(r_j - d_j)r_j^{-2}(r_j - 1)^{-1}. \qquad [5]$$

Hence the statistic $v_j' = (d_{1j} - u_{1j}, \ldots, d_{mj} - u_{mj})$ has conditional mean zero and variance V_j under the null hypothesis. The summation of these differences across failure times.

$$v = \sum_1^k v_j \qquad [6]$$

is known as the logrank statistic (Mantel, 1966; Peto and Peto, 1972). The contributions to this statistic across the various failure times are uncorrelated, and $v'V^{-1}v$ generally has an asymptotic chi-square distribution with $m - 1$ degrees of freedom where $V = \sum_1^k V_j$ and a 'prime' denotes vector transpose.

This construction also shows that a broad class of 'censored data rank tests' of the form $\sum_1^k w_j v_j$ also provide valid tests of the equality of the m survival curves. In these tests, the 'weight' w_j at time t_j can be chosen to depend on the above conditioning event at t_j, or on data collected before t_j, more generally. The null hypothesis variance of these test statistics is readily estimated by $\sum_1^k w_j^2 V_j$, again leading to an asymptotic chi-square $(m - 1)$ test statistic. The special case $w_j = \widehat{F}(t_j^-)$ generalizes the Wilcoxon rank sum test to censored data in a natural fashion (e.g., Peto and Peto, 1972; Prentice, 1978) and provides an alternative to the logrank test that assigns greater weight to earlier failure times. More adaptive tests can also be entertained (e.g., Harrington and Fleming, 1982).

Failure-Time Regression: the Cox Model

Model Development

The same type of conditional probability argument generalizes to produce a flexible and powerful regression method for the analysis of failure-time data. This method was proposed in the fundamental paper by Cox (1972) and is referred to as Cox regression or as relative risk regression.

Suppose that each subject has an associated vector of covariates $z' = (z_1, z_2,\ldots)$. For example, the elements of z may include primary exposure variables and confounding factor measurements in an epidemiologic cohort study, or treatment indicators and patient characteristics in a randomized clinical trial. Let $\lambda(t; z)$ denote the hazard rate at time t for an absolutely continuous failure time T on an individual with covariate vector z. Now one requires the censoring patterns, and the cohort entry patterns, to be such that the hazard rate $\lambda(t; z)$ applies to the cohort members at risk at follow-up

time t and covariate value z for each t and z. The Cox regression model specifies a parametric form for the hazard rate ratio$\lambda(t;\, z)/\lambda(t;\, z_0)$, where z_0 is a reference value (e.g., $z_0 = 0$). Because this ratio is nonnegative, it is common to use an exponential parametric model of the form $exp\{x(t)\beta\}$. The vector $x(t) = \{x_1(t),\ldots,\, x_p(t)\}$ includes derived covariates that are functions of the elements of z (e.g., main effects and interactions) and possibly product (interaction) terms between z and t. The vector $\beta' = (\beta_1,\ldots,\, \beta_p)$ is a p-vector of regression parameters to be estimated. Denoting $\lambda_0(t) = \lambda(t;\, z_0)$ allows the model to be written in the standard form.

$$\lambda(t;z) = \lambda_0(t)\exp\{x(t)\beta\}. \qquad [7]$$

As in previous section let $t_1 < t_2 < \cdots < t_k$ denote the ordered distinct failure times observed in follow-up of the cohort, and let d_j denote the number of failures at t_j. Also let $R(t_j)$ denote the set of labels of individuals at risk for failure at t_j^-. We suppose first that there are no ties in the data so that $d_j = 1$. The conditional probability that the ith individual in the risk set with covariate z_i fails at t_j, given that $d_j = 1$ and the failure, censoring (and covariate) information prior to t_j, is simply.

$$\frac{\lambda(t_j;z_i)}{\sum_{\ell\in R(t_j)}\lambda(t_j;z_\ell)} = \frac{\exp\{x_i(t_j)\beta\}}{\sum_{\ell\in R(t_j)}\exp\{x_l(t_j)\beta\}}. \qquad [8]$$

The product of such terms across the distinct failure times.

$$L(\beta) = \prod_{j=1}^{k}\frac{\exp\{x_j(t_j)\beta\}}{\sum_{\ell\in R(t_j)}\exp\{x_\ell(t_j)\beta\}} \qquad [9]$$

is known as the partial likelihood function for the relative risk parameter β.

If one denotes $L(\beta) = \prod_{j=1}^{k} L_j(\beta)$, then the fact that the scores $\partial \log L_j(\beta)/\partial\beta,\ j = 1,\ldots,\, k$ have mean zero and are uncorrelated (Cox, 1975) suggests that, under regularity conditions, the partial likelihood (9) has the same asymptotic properties as does the usual likelihood function. Let $\widehat{\beta}$ denote the maximum partial likelihood estimate that solves $\partial \log L(\beta)/\partial\beta = 0$. Then, $n^{1/2}(\widehat{\beta} - \beta)$ will generally converge, as the sample size n becomes large, to a p-variate norma1 distribution having mean zero and covariance matrix consistently estimated by $-n^{-1}\partial^2 \log L(\widehat{\beta})/\partial\widehat{\beta}\,\partial\widehat{\beta}'$. This result provides the usual basis for tests and confidence intervals on the elements of β.

Even though we are working with continuous models, there will often be some tied failure times. If the ties are numerous, it may be better to model the data using a discrete failure-time model. Often, however, a simple modification to (9) is appropriate.When the d_j are small compared with the r_j, the approximate partial likelihood (Peto and Peto, 1972; Breslow, 1974)

$$L(\beta) = \prod_{j=1}^{k}\frac{\exp\{s_j(t_j)\beta\}}{\left[\sum_{\ell\in R(t_j)}\exp\{x_l(t_j)\beta\}\right]^{d_j}} \qquad [10]$$

is quite adequate for inference, where $s_j(t_j) = \sum_{i\in D_j} x_j(t_j)$ and D_j represents the set of labels of individuals failing at t_j. Efron (1977) suggested an alternate approximation that is only slightly more complicated and is somewhat better. Both the Breslow and Efron approximations are available in software packages.

Special Cases and Generalizations

Some special cases of the modeled regression vector $x(t)$ illustrate the flexibility of the relative risk model (7). If one restricts $x(t) = x$, to be independent of t, then the hazard ratios at any pair of z-values are constant. This gives the important proportional hazards special case of (7). For example, if the elements of z include indicator variables for $m - 1$ of m samples and $x(t) = (z_1,\ldots,\, z_{m-1})$ then each e^{β_j}, $j = 1,\ldots,\, m - 1$ denotes the hazard ratio for the jth sample compared with the last (mth) sample. In this circumstance the score test for $\beta = 0$ arising from (9) reduces to the logrank test of the preceding section.

The constant hazard ratio assumption, in this example, can be relaxed by defining $x(t) = \{g(t)z_1,\ldots,\, g(t)z_{m-1}\}$ for some specified function g of follow-up time. For example $g(t) = log\ t$ would allow hazard ratios of the form t^{β_j} for the jth sample compared with the mth. This gives a model in which hazard ratio for the jth versus the mth population increase ($\beta_j > 0$) or decrease ($\beta_j < 0$) monotonely from unity as t increases. The corresponding score test would be a weighted logrank test for the global null hypothesis. More generally one could define $x(t) = \{z_1,\ldots,\, z_{m-1},\, g(t)z_1,\ldots,\, g(t)z_{m-1}\}$. This model is hierarchical with main effects for the sample indicators and interactions with $g(t)$. A test that the interaction coefficients are zero provides an approach to checking for proportionality of the hazard functions. Departure from proportionality would imply the need to retain some product terms in the model, or to relax the proportionality assumption in some other way.

As a second special case consider a single quantitative predictor variable z. Under a proportional hazards assumption one can include various functions of z in the modeled (time independent) regression vector $x(t) = x$ for model building and checking, just as in ordinary linear regression. The proportionality assumption can be relaxed in various ways including setting $x(t) = \{xI_1(t),\ldots,\, xI_q(t)\}$ where $I_1(t),\ldots,\, I_q(t)$ are indicator variables for a partition of the study follow up period. The resulting model allows the relative risk parameters corresponding to the elements of $x = x(z)$ to be separately estimated in each follow-up interval. This provides a means for testing the proportionality assumption, and relaxing it as necessary to provide an adequate representation of the data.

The above description of the Cox model (7) assumed that a fixed regression vector z was measured on each study subject. It is important to note that (7) can be relaxed to include measurements of stochastic covariates that evolve over time. This does not complicate the development of (9) or (10). Specifically, if $z(t)$ denotes a study subject's covariates at follow-up time t, and $Z(t) = \{z(u);\, u < t\}$ denotes the corresponding covariate history up to time t, then the hazard rate $\lambda(t;\, Z(t)\}$ can be modeled according to the right side of (7) with $x(t)$, comprising functions of $Z(t)$ and product terms between such functions and time.

Careful thought must be given to relative risk parameter interpretation in the presence of stochastic covariates. For example, the interpretation of treatment effect parameters in a randomized controlled trial may be affected substantially by

the inclusion of postrandomization covariates when those covariates are affected by the treatment. However, careful use of such covariates can serve to identify mechanisms by which the treatment works.

Survivor Function Estimation

The cumulative 'baseline' hazard function $\Lambda_0(t) = \int_0^t \lambda_0(u)\mathrm{d}u$ (7) can be simply estimated (Breslow, 1974) by.

$$\widehat{\Lambda}_0\left(t;\widehat{\beta}\right) = \sum_{t_j \le t}\left[d_j \Big/ \sum_{\ell \in R(t_j)} \exp\left\{x_\ell(t_j)\widehat{\beta}\right\}\right]. \qquad [11]$$

If $x(t) = x$ is time-independent, the survivor function $F(t; z) = p\{T > t|z\} = exp\{-\Lambda_0(t)e^{x\beta}\}$ is estimated by.

$$\widehat{F}(t;\, z) = \exp\left\{-\widehat{\Lambda}_0\left(t;\, \widehat{\beta}\right)e^{x\widehat{\beta}}\right\} \qquad [12]$$

A slightly more complicated estimator $\widehat{F}(t; z)$ is available if x is time-dependent.

A practically important generalization of (7) allows the baseline hazard to depend on strata $s = s(z)$, or more generally $s = s(z, t)$ so that

$$\lambda(t; z) = \lambda_{0s}(t)\exp\{x(t)\beta\} \qquad [13]$$

where s takes integer values 1,2,…, m indexing the strata. This provides another avenue for relaxing a proportional hazards assumption. The stratified partial likelihood is simply a product of terms (9) over the various strata.

Asymptotic Distribution Theory

The score function $U(\beta) = \partial \log L(\beta)/\partial\beta$ from (9) involves a sum of terms that are uncorrelated but not independent. The theory of counting processes and martingales provides a framework in which this uncorrelated structure can be described, and a formal development of asymptotic distribution theory. Specifically, the counting process N for a study subject is defined by $N(t) = 0$ prior to the time of an observed failure, and $N(t) = 1$ at or beyond the subject's observed failure time. The counting process can be decomposed as

$$N(t) = \Lambda(t) + M(t) \qquad [14]$$

where, under independent censorship,

$$\Lambda(t) = Y(t)\int_0^t \lambda\{u; Z(u)\}\mathrm{d}u \qquad [15]$$

and $M(t)$ is a locally square integrable martingale. Note that in the 'compensator' Λ the 'at risk' process Y is defined by $Y(t) = 1$ up to the time of failure or censoring for the subject and zero thereafter. The decomposition (14) allows the logarithm of (9), and its derivatives, and the cumulative hazard estimator (11), to be expressed as stochastic integrals with respect to martingales, to which powerful convergence theorems apply. Anderson and Gill (1982) provide a thorough development of asymptotic distribution theory for the Cox model using these counting process techniques, and provide weak conditions for the joint asymptotic convergence of $n^{1/2}(\widehat{\beta} - \beta)$ and to $\widehat{\Lambda}(\cdot, \widehat{\beta})$ to Gaussian processes. The books by Fleming and Harrington (1991) and Andersen et al. (1993) use the counting process formulation for the theory of each of the statistics mentioned above, and for various other tests and estimators.

Other Failure-Time Regression Models

Parametric Models

Parametric failure-time regression models may be considered as an alternative to the semiparametric Cox model (7). For example, requiring $\lambda_0(t)$ in (7) to be a constant or a power function of time gives exponential and Weibull regression models respectively. The maximum partial likelihood estimate $\widehat{\beta}$ of the preceding section is known to be fully efficient within the semiparametric model with $\lambda_0(t)$ in (7) completely unspecified. While some efficiency gain in β estimation is possible if an assumed parametric model is true, such improvement is typically small and may be more than offset by a lack of robustness.

Of course there are many parametric regression models that are not contained in the Cox model (7). One such class specifies a linear model for the logarithm of time to failure.

$$\log T = \alpha + x\beta + \sigma u \qquad [16]$$

where $x = x(z)$ is comprised of functions of a fixed regression vector z. The parameters α and σ are location and scale parameters, β is a vector of regression parameters and u is an error variate. Because regression effects are additive on $\log T$, or multiplicative on T, this class of models is often referred to as the accelerated failure-time model. If the error u has an extreme value distribution with density $f(u)exp(u - e^u)$, then the resulting model for T is the Weibull regression model previously mentioned. More generally, any specified density for u induces a hazard-function model $\lambda(t; z)$ for T to which standard likelihood estimation procedures apply, and asymptotic distribution theory can be developed based again on counting process theory.

A Competing Semiparametric Model

The model (16) has also been studied as a semiparametric class in which the distribution of the error u is unspecified. Prentice (1978) considered the likelihood for the censored data rank vector based on the 'residuals' $v(\beta_0) = logT - x\beta_0$ to generate a linear rank statistic.

$$\sum_{j=1}^{k}\left(x_j - \bar{x}_j\right)w_j v_j(\beta_0) \qquad [17]$$

for testing $\beta = \beta_0$. In (17), $v_j(\beta_0)$ is the jth largest of the uncensored $v(\beta_0)$ values, x_j is the corresponding modeled covariate value, $\bar{x}_j$ is the average of the x-values for the individuals having 'residual' equal or greater than $v_j(\beta_0)$ and w_j is a weight, usually taken to be identically equal to one (logrank scores). An estimator of $\widehat{\beta}$ of β in (17) can be defined as a value of β_0 for which the length of the vector (17) is minimized. The calculation of $\widehat{\beta}$ is complicated by the fact that (17) is a step function that requires a reranking of the residuals at each trial value of β_0. However, simulated annealing methods have been developed (Lin and Geyer, 1992) for this calculation, and resampling methods have been proposed for the estimation of confidence intervals for the elements of β (Parzen et al., 1994). See Ying (1993) for an account of the asymptotic theory for $\widehat{\beta}$.

The model (16) implies a hazard function of the form.

$$\lambda(t;z) = \lambda_0(te^{-x\beta})e^{-x\beta}. \quad [18]$$

This form suggests a time-dependent covariate version of the accelerated failure-time model (e.g., Cox and Oakes, 1984; Robins and Tsiatis, 1992) given by

$$\lambda\{t, Z(t)\} = \lambda_0\{\int_0^t e^{-x(u)\beta}du\}e^{-x(t)\beta} \quad [19]$$

which retains the notion of the preceding covariate history implying a rescaling or acceleration, by a factor $e^{-x(t)\beta}$, of the rate at which a study subject traverses the failure-time axis.

Multiple Failure Times and Types

Multiple Failure Types and Competing Risks

Suppose that individuals are followed for the occurrence of a univariate failure time, but that the failure may be one of several types. The type i specific hazard function at follow-up time t, for an individual having preceding covariate $Z(t)$ can, for example, be specified as

$$\lambda_i\{t; Z(t)\} = \lambda_{0i}(t)\exp\{x(t)\beta_i\} \quad [20]$$

where λ_{0i} is a baseline hazard for the ith failure type and β_i is a corresponding relative risk parameter. Estimation of $\beta_1, \beta_2, \ldots$, under independent censorship is readily based on a partial likelihood function that is simply a product of terms (9) over distinct failure types (e.g., Kalbfleisch and Prentice, 1980: Chapter 7). In fact, inference on a particular regression vector β_i and corresponding cumulative hazard function Λ_{0i} is based on (9) upon censoring the failures of types other than (i) at their observed failure times. Accelerated failure time regression methods similarly generalize for the estimation of type-specific regression parameters.

Very often questions are posed that relate to the relationship between the various types of failure. It should be stressed that data on failure time and failure type alone are insufficient for studying the interrelation among the failure mechanisms for the different types, rather one generally requires the ability to observe the times of multiple failures on specific study subjects.

Recurrent Events

Suppose that there is a single type of failure, but that individual study subjects may experience multiple failures over time. Examples include multiple disease recurrences among cancer patients, multiple job losses in an employment history study, or multiple breakdowns of a manufactured item. The counting process N at follow-up time t is defined as the number of failures observed to occur on the interval $(0, t]$ for the specific individual. The asymptotic theory of Andersen and Gill (1982) embraced such counting processes in which the failure rate at time t was of Cox model form.

$$\lambda\{t; H(t)\} = \lambda_0(t)\exp\{x(t)\beta\}. \quad [21]$$

In this expression, the conditioning event $H(t)$ includes the individual's counting process history, in addition to the corresponding covariate history prior to follow-up time t. Hence the modeled covariate $x(t)$ must specify the dependence of the failure rate at time t both on the covariates and on the effects of the individual's preceding failure history. Various generalizations of (21) may be considered to acknowledge these conditioning histories in a flexible fashion. For example, λ_0 can be stratified on the number of preceding failures on the study subject; or the argument in λ_0 may be replaced by the gap time from the preceding failure (Prentice et al., 1981).

A useful alternative to (21) involves modeling a marginalized failure rate in which one 'forgets' some aspects of $H(t)$. For example, one could replace $H(t)$ in (21) by the covariate history $Z(t)$ and the number $s = s(t)$ of failures for the individual prior to time t. A Cox-type model $\lambda_{0s}(t)exp\{x(t)\beta_s\}$ for the resulting failure rate function would allow one to focus on covariate effects without having to model the timing of the s preceding failures. While the parameters β_s can again be estimated using the score equations from a stratified version of (9) a corresponding sandwich variance formula is needed to acknowledge the variability introduced by the nonincreasing conditioning event (Wei et al., 1989; Pepe and Cai, 1993; Lawless and Nadeau, 1995).

Correlated Failure Times

In some settings, such as group randomized intervention trials, the failure times on individuals within groups may be correlated, a feature that needs to be properly accommodated in data analysis. In other contexts, such as family studies of disease occurrence in genetic epidemiology, study of the nature of the dependency between failure times may be a key research goal.

In the former situation, hazard-function models of the types described above can be specified for the marginal distributions of each of the correlated failure times, and marginal regression parameters may be estimated using the techniques of the preceding sections. A sandwich-type variance estimator is needed to accommodate the dependencies between the estimating function contributions for individuals in the same group (Wei et al., 1989; Prentice and Hsu, 1997).

If the nature of the dependence between failure times is of substantive interest it is natural to consider nonparametric estimation of the bivariate survivor function $F(t_1, t_2) = p(T_1 > t_1, T_2 > t_2)$. Strongly consistent and asymptotically Gaussian nonparametric estimators are available (Dabrowska, 1988; Prentice and Cai, 1992), though these estimators are nonparametric efficient only if T_1 and T_2 are independent (Gill et al., 1995). Nonparametric efficient estimators away from this independence special case can be developed through a grouped data nonparametric maximum likelihood approach (Van der Laan, 1996), though this estimation problem remains an active area of investigation.

Frailty Models

There is also substantial literature on the use of latent variables for the modeling of multivariate failure times. In these models, failure times are assumed to be independent given the value of a random effect, or frailty, which is usually assumed to affect the hazard function in a multiplicative (time-independent) fashion.

One of the simplest such models arises if a frailty variate has a gamma distribution. This generates the Clayton (1978) bivariate model with joint survivor function.

$$F(t_1, t_2) = \left\{F_1(t_1)^{-\theta} + F_2(t_2)^{-\theta} - 1\right\}^{-1/\theta} \qquad [22]$$

where θ controls the extent of dependence between T_1 and T_2 with maximal positive dependence as $\theta \to \infty$, maximal negative dependence as $\theta \to -1$, and independence at $\theta = 0$ (e.g., Oakes, 1989).

Nielsen et al. (1992) generalize this model to include regression variables and propose an expectation-maximization algorithm with profiling on θ for model fitting. Andersen et al. (1993) and Hougaard (2000) provide fuller accounts of this approach to multi variate failure-time analysis.

Additional Survival Analysis Topics

Space permits only brief mention of a few additional survival analysis topics: Considerable effort has been devoted to model building and testing aspects of the use of failure-time regression models. The monograph by Therneau and Grambsch (2000) summarizes much of this work in the context of the Cox model (7).

The cost of assembling covariate histories has led to a number of proposals for sampling within cohorts, whereby the denominator terms in (9) are replaced by suitable estimates, based on a subset of the subjects at risk. These include nested case–control sampling in which the denominator at t_j is replaced by a sum that involves the individual failing at t_j and controls randomly selected from $R(t_j)$, independently at each distinct t_j, and case-cohort sampling in which the denominator summation at t_j consists of the failing individual along with the at risk members of a fixed random subcohort (see Samuelson (1997) for a recent contribution).

Considerable effort has also been directed to allowing for measurement error in regression variables, particularly in the context of the Cox model (7) with time-independent covariates. Huang and Wang (2000) provide a method for consistently estimating β in (7) under a classical measurement error model, and provide a summary of the literature on this important topic.

Testing and estimation on regression parameters has also been considered in the context of clinical trials under sequential monitoring. The recent book by Jennison and Turnbull (2000) summarizes this work.

Additional perspective on the survival analysis literature can be obtained from the overviews of Anderson and Keiding (1999) and of Oakes (2000). Goldstein and Harrell (1999) provide a description of the capabilities of various statistical software packages for carrying out survival analyses.

Abstract

In this article, we introduce methods for addressing questions about the occurrence and timing of critical events in a person's life. Such questions are typically framed by asking whether and, if so, when the event will occur? Examples range from the occurrence and timing of macro-events such as high school graduation and dropout, marriage, abortion and divorce, onset of depression and relapse into drug and alcohol abuse, and so forth.

We discuss key issues in the design of event-history data collection and the ubiquitous problem of censoring that renders standard quantitative data analyses inhospitable for such data. We distinguish two approaches – discrete-time and continuous-time survival analysis – and focus on the former because of its conceptual clarity, flexibility, and ease of application. Throughout the article, we illustrate each step in this process using a running example of the occurrence and timing of first divorce in Wisconsin, in the latter half of the twentieth century. We end by revealing compelling extensions of the basic approach to the case of time-varying predictors, repeated spells, competing risks, and continuous-time methods. We suggest follow-up readings.

Scholars in the social and behavioral sciences often investigate the occurrence and timing of critical events in a person's life. Developmentalists pose questions about whether a child has achieved some moral, affective, or cognitive milestone, and by what age. Psychiatrists seek to understand the occurrence and timing of suicide, or relapse into drug abuse. Educators map out the patterning of school dropout and graduation, or entry into and exit from college. Whatever the nature of the underlying event, their questions all deal with the occurrence and timing of critical events. They inquire whether a critical event (such as relapse into drug abuse or first experience of sexual activity) has occurred, and if it occurred, then when. Beyond this, we also usually want to know how answers to such questions differ by features of participants' backgrounds, life experiences, treatment, and the like. For instance, when investigating the event of relapse into drug abuse, psychiatrists may want to confirm that the patterning of relapse differed for addicts who had been assigned to an innovative treatment versus those who were not. These are all questions about systematic interindividual differences in the patterning of critical events in a person's life.

In this article, we illustrate how survival (or event-history) analysis can be used to address these questions. Even though we refer to these methods as 'survival' analysis, they are ideal for investigating the occurrence and timing of any event that can be defined clearly and observed cleanly, both those that are of 'negative' consequence (e.g., death, divorce) and those that are 'positive' (e.g., birth of a first child, achievement of life goals). In presenting the methods, we use longitudinal data from the Wisconsin Longitudinal Study (WLS). This dataset contains data on a random and representative sample of 10 317 men and women in Wisconsin, followed from high school graduation in 1957 through 2004, with follow-ups in 1957, 1964, 1975, and 1992. We focus on the subsample of 7860 participants who entered into a first marriage during this period, some of whom divorced and some who did not. For this group, we also know their educational attainment on entry into the marriage (recorded as values of the dichotomous predictor, *DEGREE*, and coded 1 if the participant possessed a bachelor's degree at the start of the marriage, 0 otherwise).

Three Design Decisions That Underpin Survival Analysis

To study event occurrence, you must first define the event whose occurrence you wish to investigate. Events occur when someone makes a transition from one 'state' to another. In a survival-analytic application, these bounding states must be mutually exclusive and exhaustive. In our example, for instance, the two states in question are 'in a first marriage' versus 'divorced from a first marriage.' We are not saying that divorce is the only way a marriage can end – clearly, the death of either partner would also suffice. Nor are we saying that survival methods apply only in situations where such an either/or choice exists. The basic survival-analytic approach can be extended to situations in which folk can occupy three or more states, or in which a transition is repeated over and over. A single on/off event is a good place to start. Thus, here, we ask whether those who entered a first marriage in Wisconsin in the latter half of the twentieth century experienced a first divorce and, if so, when?

After defining the event of interest, you must also specify an occasion to be your 'origin' or 'beginning of time.' At this moment, everyone in the population must occupy the first of the two possible states, so that no one has yet experienced the event but is eligible to do so. In the language of survival analysis, you start the clock when everyone is 'at risk' of experiencing the event. In our example, participants are 'at risk' of experiencing a first divorce once they enter a first marriage, and so our 'beginning of time' is the date of the first marriage.

Next, you must decide on the scale you will use to measure time. Sometimes, time can be recorded very precisely. For example, we might know the exact number of days that a first

marriage lasted if we knew the explicit dates of marriage and divorce. Unfortunately, our WLS dataset provides only the years in which these milestones occurred, and so we measure the duration of the marriage very coarsely. In survival analysis, we distinguish between lifetimes recorded in narrow precise units and those recorded in coarser intervals by referring to the former as continuous-time data versus the latter discrete-time. Despite the obvious advantages of measuring everything as precisely as possible, scholars often find themselves with discrete-time data, as we do in our data example here. Some events may occur only at discrete points in time. Prospective students, for example, can often only graduate from college at preset times during the year. Or, financial or data-collection constraints may force researchers to use discrete intervals to record the passage of time to the nearest month or year.

The distinction between the continuous- and discrete-time approaches to survival analysis is not cosmetic. Every aspect of the process – the specification of statistical models, their parameter definition, methods of estimation, the testing, and interpretation – all depend on this choice. In this article, we focus on methods for event-history data collected in discrete time. In our conclusion, we comment on the extension to continuous-time methods.

The Ubiquitous Problem of Censoring

Whenever you investigate event occurrence, you face a difficulty that is not encountered by scholars working with other kinds of outcomes. What should you do with participants who do not experience the target event while you are observing them? In our WLS dataset, for instance, most of the participants whose first marriages were tracked did not divorce at all by 2004, the last year of data collection. Thus, for them, we have no information on the very 'time-to-divorce' that we wish to investigate and summarize. These are the censored cases (Cox and Oakes, 1984; Kalbfleisch and Prentice, 1980).

You cannot ignore censored respondents in analyses of 'time-to-divorce' because the very fact that their first marriages exceeded the length of data collection tells you much about the time to divorce, the event at the center of the research. Thus, although you do not know whether the event of first divorce ever occurred for the censored cases, perhaps after data collection was ended, you must incorporate this information legitimately into your summary statistics, for the latter to be credible (unbiased). For instance, to estimate the average length of a first marriage, in Wisconsin, we would need to include both uncensored and censored cases in your estimation; otherwise, we would be ignoring many of the folk with the longest marriages, longer than the period of data collection. To estimate such a statistic, it seems as though we must impute some sensible value of 'time-to-first-divorce' for the censored cases simply to retain them in our estimation, even though they never experienced the event while we watched. Otherwise, they would wind up excluded. But, what imputed value of 'time-to-divorce' would be most appropriate, and does assigning an arbitrary imputed value make sense, given that many of them may never divorce at all?

This is the conundrum at the heart of investigating event occurrence. No matter when data collection begins and how long it lasts, some members of the sample will be censored and have unknown event times. How can we remain true to the research question and have our findings reflect the representative sample with which we began the research? It is the resolution of this problem that is the centerpiece of survival analysis. The solution follows.

First, however, think about the mechanisms by which censoring occurs. In any study, the amount of censoring depends on two things. It depends on the rate at which events occur and on the length of data collection. If the event of interest is common and your data collection is long, then most participants in your sample may experience the event while you watch. There will be very few censored cases. On the other hand, if the event of interest is rare or your data collection curtailed, then censoring will be widespread. In our WLS dataset, even though data collection lasted decades, the target event – divorce from a first marriage – was not common. Among the 7860 respondents in our analytic subsample of 'first marrieds,' a huge number – 6826 – did not experience divorce while watched and were therefore censored.

Censoring is also exacerbated by other features of the event-history process under investigation. For instance, in addition to being censored if they remained in their first marriage at the end of data collection in 2004, participants in Wisconsin were censored for two other reasons. First, they could not still be married if either they or their spouses died during data collection. Therefore, in our data, partners who died or experienced the death of a spouse were also censored, not by the end of data collection but at the year of their spouse's death. Second, in large longitudinal studies like our WLS survey, respondents disappear via attrition. In our case, almost one-third of respondents were missing data in the last wave of data collection (2004). But, many of them had responded legitimately in the previous wave, and so their event histories are censored in 1992.

The most critical distinction is whether censoring was noninformative or informative. A noninformative censoring mechanism operates independently of the risk of event occurrence and is exogenous to it. Thus, if censoring is determined in advance by design or by the ending of grant funding, say, then it is noninformative. On the other hand, it would not be the case if participation in the study was ended because of endogenous actions taken by study participants (i.e., if they chose when they stopped participating) or because of unanticipated consequences of the study's outcomes that then impacted the research design retroactively (as when the evaluation of a drug treatment is cut short because of the declining health of some participants). If censoring is noninformative, we can assume that participants have been censored at random, and consequently the sample of uncensored participants who continue into the following time period remains representative of the population from the sample that was drawn in the previous period.

If censoring pops up in ways connected to the event occurrence itself, then censoring is informative and the unbiasedness of your analysis is threatened. For instance, let us suppose you conduct a study of time-to-relapse following treatment for cocaine abuse, contacting former addicts monthly to inquire if they are still abstinent. During your 2-year follow-up, you find that some of the former addicts are censored because

they stopped responding to your outreach. If this attrition was unrelated to their former habit, the censoring would remain uninformative. However, if they had relapsed to drug abuse and as a consequence stopped responding to you, through embarrassment or by dropping off the social map, then censoring would be informative, and connected to the occurrence of the event. In this case, you could no longer assume that the subsample of folk who remained uncensored after each wave of data collection continues to be representative of the participants in the preceding time interval, and your estimation of time-to-event will be challenged. No survival-analytic strategy can produce unbiased estimates of event occurrence and timing if censoring is informative.

Exploring Event Occurrence in Discrete-Time Data

The presence of censoring in event-history data makes standard statistical tools such as the estimation of means, the fitting of linear regression models, and so on inappropriate. This is because the presence of censoring indicates that important outcome information is absent for a legitimate portion of the sample. While you know that a censored individual did not experience the target event by the time of censoring, you do not know when s/he will experience it ultimately, if at all. Consequently, you do not have a value for what appears to be the conceptual outcome featured in the research question; you do not know the 'when,' the requisite time-to-event, for the censored person. The resolution that underpins survival methods is that while continuing to focus on the central notion of time-to-event, you must abandon statistics such as the sample mean and linked strategies like linear-regression analysis because they become meaningless in the face of censoring.

Instead, we focus on innovative approaches requiring the definition of new quantities known as the *hazard probability*, the *survival probability*, and the *median lifetime*, each of which can be estimated unbiasedly in the presence of censoring (Allison, 1984). These three new parameters are easily comprehended via an example of life-table analysis, a traditional technique for summarizing event-history data. It is useful not only for introducing the concepts of survival analysis but also for exploring discrete-time event-history data before embarking on model fitting and statistical inference to address your research questions formally.

In Table 1, we present a life table summarizing the occurrence of first divorce, among 'first marrieds' from Wisconsin. Having defined the start of the first marriage as the 'beginning of time,' we have constructed the table so that, following this inauguration, there is one row for each of the discrete-time 4-year intervals observed. Incidentally, we carved up the passage of time into these coarser 4-year discrete-time periods to reduce the complexity of subsequent statistical models, and then later confirmed that our conclusions were robust to the choice. In establishing the coarsening, we wanted to make sure that at least one person experienced the event of interest within each bin in order to avoid later difficulties in estimation. Finally, because no one in our first-married sample who remained married for more than 44 years actually got divorced before the end of data collection, we truncated the marriage span at 44 years (after 11 discrete 4-year time periods). We label the discrete-time intervals in the first two columns. There are 11, labeled intervals from '1' through '11.' We have used a standard notation (Singer and Willett, 2003) of an opening bracket '[' and a closing parenthesis ')' to indicate that each interval includes the start time and runs up to, but does not include, the closing time. Thus, interval [1, 4) includes the first day of the first year of marriage and runs up through the last day of the fourth year of marriage, and so on.

In the next three columns, we list frequencies that summarize event distribution in the sample, including the number of participants who entered each time interval still married (Column #3), the number who experienced a first divorce during the time interval (Column #4), and the number who were censored by the end of the time period (Column #5). All 7860 participants are in their first marriage at the beginning of time, and therefore 'at risk' of experiencing the event of interest, a first divorce. Then, during the first discrete-time interval (first 4 years of marriage), 150 participants divorced

Table 1 Life table displaying the sample distribution of divorce among the first married in Wisconsin, as a function of time (partitioned into discrete 4-year time periods)

		Number of participants…			*Proportion of participants…*	
Time period	*Covered duration (years)*	*In a first marriage at the beginning of each time period (risk set)*	*Divorced during the time period*	*Censored at the end of the time period*	*In a first marriage at the beginning of the time period, and divorced during it (hazard probability)*	*Still married at the end of the time period (survival probability)*
1	(1, 5)	7860	150	6	0.019	0.981
2	(5, 9)	7704	253	26	0.033	0.949
3	(9, 13)	7425	258	74	0.035	0.916
4	(13, 17)	7093	190	204	0.027	0.891
5	(17, 21)	6699	43	217	0.006	0.886
6	(21, 25)	6439	17	108	0.003	0.883
7	(25, 29)	6314	12	209	0.002	0.882
8	(29, 33)	6093	20	382	0.003	0.879
9	(33, 37)	5691	36	639	0.006	0.873
10	(37, 41)	5016	43	820	0.009	0.866
11	(41, 45)	4153	12	2061	0.003	0.863

and 6 were censored, leaving 7704 (=7860 − [150 + 6]) to enter the next interval. Of these, in their turn, 253 divorced and 26 were censored, leaving 7425 individuals to enter the third discrete-time interval and so on.

In survival analysis, we refer to those first marrieds who entered each successive discrete-time period as the risk set for that period, to indicate that they were eligible for or 'at risk' of experiencing a first divorce in that period. At the beginning of each discrete-time interval, the risk set contains everyone from the prior period's risk set minus those who divorced or were censored in the prior period. The definition of the risk set is inherently conditional. Any participant, in the risk set in any particular period, can only experience first divorce (or be censored) in that time period if s/he has not experienced it, nor been censored, in a prior period. Once s/he has experienced the event, or been censored, s/he disappears from the risk set for all future periods. This conditionality is a centerpiece of subsequent data summaries because it permits folk to contribute to those summaries up to their last moment of eligibility, regardless of termination by divorce or censoring.

We can define the 'risk' of event occurrence in any discrete-time period by defining the hazard probability, a summary that remains credible in the face of censoring (Allison, 1984). It is the conditional probability that someone will experience the event of interest during a particular discrete-time period, given that s/he did not already experience it, in an earlier period. As usual, hazard probability is defined in the population as a parameter and then estimated in the sample. Thus, in the population, the hazard probability is

$$h(t_{ij}) = \Pr[T_i = j | T_i \geq j] \qquad [1]$$

where T is a discrete random variable whose values identify the time period j in which an individual i can experience the event. The logic of the definition is that it stipulates hazard as the probability that the event occurs in the jth discrete time period, given that it must occur in this, or some future, period – in other words, that it had not occurred earlier. A list of discrete-time hazard probabilities, for all j, in the population is referred to as the *discrete-time hazard function*.

We can obtain maximum-likelihood estimates of the discrete-time hazard probabilities straightforwardly, by computing the sample proportions of participants who were at risk at the beginning of each time period and who experienced the event by the end of the time period (Allison, 1984). These sample hazard probabilities describe the pattern of first divorce in Wisconsin (Column #6). For example, during time period #1, out of 7860 high school graduates who entered a first marriage, 150 divorced before their fourth anniversary, at the end of the first period. Thus, the estimated hazard probability is 0.019 (or 150/7860) in this period. At the end of the period, six respondents had also been censored, leaving 7704 (or 7860 − [150 + 6]) participants, now married for at least 4 years, to enter the risk set in the second discrete-time period. Of these, 0.033 (or 253/7704) then divorced before their eighth anniversary, providing the estimated hazard probability in the second period, and so on.

We plot these estimated discrete-time hazard probabilities against time to provide the estimated hazard function, in the top panel of **Figure 1**. In the figure, we have adopted some conventions. First, we have plotted the estimated risks vertically

Figure 1 Sample hazard and survivor functions displaying the risk of first divorce as a function of the duration of a first marriage (scaled in discrete 4-year periods) (from **Table 3**).

above the number of full years of marriage that had occurred by the end of each period. Thus, even though the first period is labeled as [1, 5) in **Table 1**, the estimated hazard probability for the first period is plotted at '4 years' to indicate that 4 years of marriage had passed by the end of this period. Second, we joined the plotted points by line segments to suggest an envelope of risk (Miller, 1980).

Inspection of the estimated hazard function helps identify especially risky time periods, when respondents will most likely experience a first divorce. For instance, the estimated hazard function rises over the first three discrete time periods, peaking at 0.035 after 12 years. In other words, among participants who remain in first marriages for 12 years, 3.5% divorce in the third time period. Then, the estimated hazard function drops dramatically, and risk of divorce between 20 and 32 years of marriage is almost zero. Finally, there is a second lower peak at around 40 years, suggesting a marginally greater risk of divorce later in marriage.

You can also cumulate this period-by-period risk information and redisplay it in a second profile, the survivor function, to describe the distribution of event occurrence over time in an alternative way (Allison, 1984). The population survival probability, $S(t_{ij})$, is the probability that an individual i will survive beyond a particular time period j in the population. With no censoring, survival probability at any time can be estimated directly by computing the proportion of individuals who have not experienced the target event by the end of the requisite discrete-time period. However, when censoring is present, we use an indirect approach to estimate the survival probability in each time period:

$$\widehat{S}(t_j) = \widehat{S}(t_{j-1})\left[1 - \widehat{h}(t_j)\right] \qquad [2]$$

Here, the estimated survival probability in any time period (j) equals the estimated survival probability in the previous

time period ($j-1$) multiplied by the complement of the estimated hazard probability for the current time period (j). The logic is straightforward. For instance, the survival probability at the start of the first period is 1.000 by definition, because all marriages must be intact at the beginning of time. By the end of that time period (year 4 of marriage), 0.981, or 98.1%, of the respondents had not yet divorced. We know this because, during this period, the estimated hazard probability is 0.019 and so this proportion of the entering risk set did divorce and its complement ($1-0.019$) did not. Since the period began with everyone at risk (survival probability of 1.000), we know that 0.981 out of 1.000, or 0.981, must have survived the period undivorced and continued into the second period. The algorithm can then be executed sequentially, over successive periods. Thus, we enter the second period with 0.981, or 98.1% of first marrieds surviving. During the second period, 0.033 of the entering risk set experienced the event of interest, and so ($1-0.033$), or 0.967 of them, did not. Thus, at the end of the second period, a proportion of 0.967 of the original 0.981 (0.949) remained undivorced, and so on.

Graphing the estimated survivor function over time summarizes trends in event occurrence visually (bottom panel of Figure 1). While its slope is always negative, the shallowness of the slope between 0 and 4 years indicates that most marriages 'survive' during this period. Between years 4 and 16, the function declines more steeply, reflecting the larger risk of first divorce here. By the end of year 16 of a first marriage, 89% of our participants have not yet divorced. The remainder of the estimated survivor function is then relatively flat, with another slight dip between years 36 and 40, where risk of a first divorce again elevated slightly.

It can be useful to provide a single number summary in response to the question, 'How long does a first marriage typically last in Wisconsin?' If there were no censoring, event times would be known for everyone and a sample average time to divorce could be computed. But, in the face of censoring, we need an estimate of central tendency that respects the long-time presence of undivorced participants in the sample. The median lifetime is suitable for this purpose and is the time by which the survival probability falls to exactly one-half. It can be estimated by constructing a line across the estimated survivor function (Miller, 1980), at a probability of 0.5, and then projecting downward onto the time axis. By the median lifetime, half of all first married have divorced and half have not. Unfortunately, here, marriages last so long that the 50–50 point is never reached during data collection, and we cannot estimate a median lifetime. However, we can estimate other quantiles instead, such as a '90th Percentile Lifetime,' which, by inspection in Figure 1, is around 12.5 years.

Specifying and Fitting Statistical Models for the Discrete-Time Hazard Probability

Life-table analysis provides useful summaries of the event history, even when censoring has occurred. More intriguingly, these same estimates of risk can be replicated by formatting the event-history data in a special way – in a person-period dataset – and conducting standard logistic-regression analyses in that dataset. We illustrate this strategy below. It not only replicates our life-table results but also provides a regression-like framework within which event occurrence can be investigated formally, with predictors of risk incorporated into the statistical model and supported by the tools of statistical inference. This latter strategy is known as discrete-time hazard modeling (Allison, 1984).

Formatting the Event-History Data in a Person-Period Dataset

To engage the new approach, you must first format your event-history data in a person-period format, in which each participant contributes one record (row) for each time period that they are at risk of the event of interest. In Table 2, we present an example of event-history data, for three folk in our sample. The first two participants divorced before the end of data collection and are therefore not censored; each has a known divorce time. The first (#1025) divorced during the second 4-year

Table 2 Fragment of a person-period dataset containing event-history data on the duration of a first marriage (in discrete units of 4 years) for three participants who began a first marriage in Wisconsin between 1957 and 2004 and whose marriages were terminated either by divorce or censoring, with information on whether they entered the marriage with a bachelor's degree

ID	*Period*	*P1*	*P2*	*P3*	*P4*	*P5*	*P6*	*P7*	*P8*	*P9*	*P10*	*P11*	*Divorce*	*DEGREE*
1025	1	1	0	0	0	0	0	0	0	0	0	0	0	0
1025	2	0	1	0	0	0	0	0	0	0	0	0	1	0
1050	1	1	0	0	0	0	0	0	0	0	0	0	0	0
1050	2	0	1	0	0	0	0	0	0	0	0	0	0	0
1050	3	0	0	1	0	0	0	0	0	0	0	0	0	0
1050	4	0	0	0	1	0	0	0	0	0	0	0	1	0
1078	1	1	0	0	0	0	0	0	0	0	0	0	0	1
1078	2	0	1	0	0	0	0	0	0	0	0	0	0	1
1078	3	0	0	1	0	0	0	0	0	0	0	0	0	1
1078	4	0	0	0	1	0	0	0	0	0	0	0	0	1
1078	5	0	0	0	0	1	0	0	0	0	0	0	0	1
1078	6	0	0	0	0	0	1	0	0	0	0	0	0	1
1078	7	0	0	0	0	0	0	1	0	0	0	0	0	1

discrete-time period, between 4 and 8 years after marriage, and the second (#1050) divorced between 12 and 16 years after marriage, in their fourth discrete-time period. On the other hand, the third participant (#1078), who married in 1977, had not gotten divorced by the end of data collection in 2004 and so was censored at the end of their seventh time period. To record this information, the person-period dataset includes a variable, *PERIOD*, to label the time period j to which each record (row) refers, ranging from 1 to 7, in this case. In the dataset, we have also described the particular time period to which each record refers by including a vector of dichotomous time-indicator variables, P_1 through P_{11}. If the row corresponds to the first period of the record for a particular participant, then the value of indicator P_1 is 1, and P_2 through P_{11} are zero. In the second row for any person, indicator P_2 has been set to 1 (and all others to zero), and so on. Later, we use these dichotomous indicators in our discrete-time hazard models to provide a general specification for time.

Our person-period dataset also contains an explicit dichotomous event indicator, *DIVORCE*, to describe whether first divorce occurred, during each discrete-time period (=1; 0 otherwise). Because of the conditionality implicit in our definition of risk, for each person who ultimately divorces (such as #1050), the value of the event indicator must be 0 in every record except the last one, in which the divorce occurred, and there it is set to 1. Whereas censored folk (like #1078) never experience a first divorce in any time period, for them, the value of *DIVORCE* remains 0 throughout all their records. Finally, the values of other important variables, potential predictors of risk, can also be recorded in the person-period dataset. In our case, we have included hypothesized dichotomous predictor *DEGREE*, whose values record whether the participant entered their first marriage with (=1) or without (=0) a college degree. Notice that, by virtue of its definition, the values of this predictor are time invariant and remain identical across all the rows contributed by each particular individual. However, it is also easy to imagine how the values of a time-varying predictor might also be recorded straightforwardly in the person-period dataset, with values that differed across the rows within person.

Fitting an Initial Discrete-Time Hazard Model in the Person-Period Dataset

If you imagine the complete person-period dataset of which Table 2 is a fragment, you will recognize that questions about whether, and if so when, first divorce occurs in Wisconsin are simple questions about the hypothesized relationship between the dichotomous outcome *DIVORCE* and time. Consequently, you can address this question by conducting a logistic-regression analysis of the relationship between *DIVORCE* and one of the specifications for time – either the linear effect of *PERIOD* or the general specification of time using indicators P_1 through P_{11} – in the person-period dataset. You would fit the following hypothesized discrete-time hazard model:

$$h(t_{ij}) = \frac{1}{1 + e^{-(\alpha_1 P_{1ij} + \alpha_2 P_{2ij} + \alpha_3 P_{3ij} \ldots + \alpha_{11} P_{11ij})}} \qquad [3]$$

Usefully, you can manipulate this model algebraically into a mathematically equivalent 'logit-hazard' specification, becoming

$$\begin{aligned} \text{logit } h(t_{ij}) &= \log_e \left\{ \frac{h(t_{ij})}{1 - h(t_{ij})} \right\} \\ &= \alpha_1 P_{1ij} + \alpha_2 P_{2ij} + \alpha_3 P_{3ij} \ldots + \alpha_{11} P_{11ij} \end{aligned} \qquad [4]$$

where 'logit' defines the natural logarithm of a probability (h) divided by its complement ($1 - h$) or as the log-odds of divorce occurrence (Singer and Willett, 2003).

Notice that we have not included a formal intercept in either specification. Such a 'no-intercept' specification is always available, in any statistical model, providing that other facets of the model are present to play the role. Here, instead of including a single overarching intercept (and omitting one of the time dummies to create a reference category), we have included several α parameters (α_1–α_{11}) to serve as multiple intercept terms, each capturing the risk of a first divorce during the corresponding discrete-time period. Parameter α_1 describes the logit-risk, or log-odds, of divorce in the first time period, α_2 in the second time period, α_3 the third, and so on. This model is our initial 'time-only' discrete-time hazard model.

Be assured of the veracity of our claim that standard logistic-regression methods can be used to fit this initial discrete-time hazard model, in the person-period dataset, and provide unbiased estimates of risk, along with suitable estimates of precision, fit, and inference. This claim is valid even though the model contains no explicit residual (as does a linear-regression model, say) and even though the data in the person-period dataset are multilevel in structure, with multiple rows being contributed by each person. The omission of an explicit 'residual' term is standard in regular logistic-regression models (Hosmer and Lemeshow, 2000) because any required uncertainty in the outcome is introduced, not by including an unobserved residual (with assumed distributional properties) but by the formulation of the outcome as a probability. In addition, interconnections among the unobserved components of the outcome, across the multiple rows of data within a person, are embedded implicitly in the model by our definition of the outcome as a conditional probability. We provide a formal proof of this claim in our companion technical paper (Singer and Willett, 1993). Consequently, you can use any standard logistic-regression routine from any statistical package to fit the models, provided your data are recorded in the person-period format. In this article, we used PROC LOGISTIC in SAS.

Recovering Estimated Hazard Probability from a Fitted Initial Discrete-Time Hazard Model

Having fitted the initial discrete-time hazard model in eqn [3] or eqn [4], you can recover period-by-period maximum-likelihood estimates of the hazard probabilities as fitted values. In the fourth column of Table 3, we list the estimated α intercept parameters. These are period-by-period estimates of the initial 'logit-hazards.' Although they are all negative (because the corresponding fitted hazard probabilities are less than 0.5), their increasing values for time periods 1–3 demonstrate an increase

Table 3 Parameter estimates and fitted hazard probabilities from an initial fitted discrete-time hazard model in which the risk of first divorce is presented as a function of a general specification of time, measured in discrete periods of 4 years ($n = 7860$)

Discrete-time period	*Predictor*	*Parameter*	*Parameter estimate* $(\widehat{\alpha}_j)$	*Fitted hazard probability* $\widehat{h}(t_j) = \frac{1}{1+e^{-\widehat{\alpha}_j}}$
1	P1	α_1	−3.940	0.019
2	P2	α_2	−3.383	0.033

in the risk of divorce, followed by a decrease through time period 7, a slight uptick through time period 10, and an eventual downtick in time period 11. We have then converted the parameter estimates from their 'log-odds' form into fitted hazard probabilities. Substituting respective values for dichotomous time indicators, P_1 through P_{11}, into the logistic-model specification in eqn [3], the fitted hazard probability in discrete-time period j is

$$\widehat{h}(t_j) = \frac{1}{1 + e^{-(\widehat{\alpha}_j)}} \qquad [5]$$

Substituting estimated values of the α parameters into eqn [5], we obtain the fitted hazard probabilities in Column #5. They are identical to the life-table estimates in Table 1.

Adding Substantive Predictors to the Initial Discrete-Time Hazard Model

The fact that you can obtain equivalent estimates of risk using logistic-regression analysis in the person-period dataset has an important ramification. It means that you now have a regression-like framework for addressing questions about 'Whether, and if so, when?' In particular, this discrete-time hazard modeling approach can be extended to include the effects of additional substantive predictors, to test hypotheses about their impact on event occurrence. For example, we can investigate whether the risk profile of divorce differs between those who were more or less educated, at the point of marriage, by adding dichotomous predictor *DEGREE* to distinguish between those who had received a bachelor's degree on entry into marriage versus those who had not, as follows:

$$\text{logit } h(t_{ij}) = (\alpha_1 P_{1ij} + \alpha_2 P_{2ij} + \alpha_3 P_{3ij} \ldots + \alpha_{11} P_{11ij}) + \beta_1 DEGREE_i \qquad [6]$$

Here, parameter β_1 represents the hypothesized influence of educational attainment on the logit-hazard function, quantifying the overarching difference in logit-hazard between participants who entered their marriages with, and without, bachelor's degrees.

Table 4 Parameter estimates and approximate *p*-values for three fitted discrete-time hazard models in which the risk of a first divorce depends on the duration of the first marriage (in discrete periods of 4 years) and whether the participant possessed a bachelor's degree on entry into the marriage ($n = 7860$)

∼p < .10; * p < .05; ** p < .01; *** p < .001.

We report parameter estimates and fit statistics for this new model in the third column of Table 4, as Model B. For comparison, we also include parallel statistics from our initial discrete-time hazard model fit, as Model A. Parameter β_1 has an estimated value of −0.516 in Model B. Because the estimate is negative, we know that the logit-hazard function for folk who were more educated on entry into marriage is lower in elevation than for those less educated. We illustrate this in the top panel of Figure 2, plotting the fitted logit-hazard profiles by group. The estimated logit-hazard profile for prototypical participants who had college degrees at marriage sits 0.516 points, on the logit-hazard scale, below that of folk without degrees, at every time point.

You can antilog a logistic-regression parameter estimate to provide an estimated odds ratio (Hosmer and Lemeshow, 2000). Here, antilogging −0.516 we obtain 0.597, which contrasts the odds of divorce in the college-degree-at-marriage group (numerator of the ratio) with the same odds in the no-degree group (denominator of the ratio). Generally, because it is easier to interpret an odds ratio that is greater

Figure 2 Fitted logit-hazard and hazard functions displaying the risk of a first divorce, in Wisconsin, as a function of first-marriage duration (in discrete periods of 4 years) for prototypical participants who had attained a bachelor's degree prior to entering into marriage (dashed profile) and did not (solid profile) (from fitted Model B, containing only the main effect of *DEGREE*, in **Table 4**).

than 1, we can flip this over to give an estimate of 1.68 (=1/0.597) and reinterpret. The estimated odds of a first divorce for a prototypical participant with no college degree at marriage are 1.67 times the odds for one with a college degree – risks of divorce are higher among the less educated, on entry into marriage. Typically, in any fitted logistic-regression model, each parameter estimate is accompanied by a single-parameter test, based on the z-statistic obtained by dividing the estimate by its standard error (or the equivalent Wald (χ^2) statistic, which is its square). In **Table 4**, we have not listed standard errors and z-statistics, to save space. But, in Model B, the standard error of $\widehat{\beta}_1$ was 0.106, and the z-statistic 4.89 ($p < .001$). We do list the latter approximate p-value as a superscript on the estimate, in the table, concluding – with great confidence – that there was a relationship between the main effect of *DEGREE* and risk of divorce, among first marrieds in Wisconsin.

We have added one more panel to **Figure 2**. In it, we have antilogged and detransformed to plot fitted hazard functions for prototypical participants who did, and did not, possess college degrees at marriage. Regardless of group, the profile of risk has a higher 'early' peak around 8–12 years of marriage and a lower 'later' peak around 36–40 years of marriage. However, the groups differ in their risk. Specifically, the estimated (hazard) probability of divorce during the first peak-risk period is around 4% (0.037) for folk with no degree at marriage, and about 2% (0.022) for those with degrees, given no divorce in a prior period.

One difference between the two panels is a consequence of the antilogging and detransforming that converted the fitted logit-hazard values in the top panel into the fitted hazard probabilities of the middle panel. This transformation underpins a ubiquitous property of these models. The inclusion of the main effect of *DEGREE* in the discrete-time hazard model seems to have simply shifted the fitted lower risk function ($DEGREE = 1$) vertically, and en bloc, to become the upper function ($DEGREE = 0$) in logit-hazard space. However, the same transition shows up as a magnification of the risk profiles in the space of hazard probabilities (bottom plot). In the latter, the vertical separation of the profiles is no longer identical in each time period. These visual differences are a mathematical property of the specification of the logistic model. (Actually, the magnification evident in the bottom panel is approximate, and true at low levels of risk, for hazard probabilities of a few percent. In reality, it is the corresponding odds profiles that are magnified with respect to one another, or proportional, because they are exponentiated versions of the corresponding vertically shifted logit-hazard functions.)

Adding Interactions between a Substantive Predictor and Time to a Discrete-Time Hazard Model

The parallel estimated logit-hazard functions in the upper panel of **Figure 2** imply that the effect of *DEGREE* on logit-risk is identical in every time period. This is often referred to as the proportional-odds assumption (Allison, 1984). This homogeneity of effect was compelled by our decision to include predictor *DEGREE* in eqn [6] only as a main effect. But, it is possible that the predictor's effect could differ from time period to period, particularly over a large portion of the human lifetime. Fortunately, we can relax this potentially unrealistic constraint by including statistical interactions between the predictor and time into the discrete-time hazard model, as follows:

$$\begin{aligned}\text{logit } h(t_{ij}) = &(\alpha_1 P_{1ij} + \alpha_2 P_{2ij} + \ldots + \alpha_{11} P_{11ij}) \\ &+ (\beta_1 DEGREE_i \times P_{1ij} + \beta_2 DEGREE_i \times P_{2ij} \\ &+ \ldots \beta_{11} DEGREE_i \times P_{11ij})\end{aligned} \quad [7]$$

Here, we have elected to drop the main effect of *DEGREE* and have, instead, included its two-way interactions with all of the time period indicators (rather than retaining the main effect of *DEGREE* and dropping one of the interaction terms, to avoid multicollinearity). From an interpretive perspective, we prefer this latter specification. In eqn [7], the original 'multiple intercept' α parameters now represent the population logit-hazard function of a 'baseline' group of persons who entered marriage without a college degree ($DEGREE = 0$). The new β parameters capture the unique interval-by-interval deviations in logit-hazard between this baseline group and those with a college degree at marriage ($DEGREE = 1$). Because there are 11 such interaction terms, spanning the observed period of marriage, the impact of *DEGREE* on the logit-risk of divorce can then be unique to each time interval. The parameter estimates and fit statistic for this new model are presented as Model C, in **Table 4**. Ironically, we could not actually estimate the last

interaction term, between *DEGREE* and time in the final period (#11), because during this last time period, no one who divorced had a college degree.

To test whether the proportional-odds assumption has been violated, we can use general linear hypothesis (GLH) testing to compare fitted models B and C. This will allow us to check whether the addition of the *DEGREE* by time interaction terms have made a statistically significant contribution to goodness-of-fit, as summarized by the −2LL statistic. In this particular comparison, we refer to Model C, with the greater number of parameters, as the 'full' model, and to Model B as the 'reduced' model (because we could constrain some of the parameters in Model C to zero, and 'reduce' it to become Model B). While the magnitude of the −2LL statistic itself is difficult to interpret directly, it is an index of 'badness-of-fit' – the worse the fit of a model, the higher the value of the −2LL statistic. Here, the −2LL statistic increases in magnitude from 9922.56 in the full model (C) to 9968.8 in the reduced model (B), a difference of 46.24, documenting the worsened fit of the simpler model on omission of the *DEGREE* by time interactions. However, is 46.24 a 'big' difference? In large samples, under maximum-likelihood theory, differences in the −2LL statistic between nested models have a χ^2 distribution with degrees of freedom equal to the number of additional parameters added to the full model to represent the additional hypothesized effect. In this case, we have added nine parameters (the difference between the 21 parameters in Model C and the 12 in Model B). The critical value of a χ^2 distribution with 9 degrees of freedom, at a Type I error of 0.05, is 16.92, which is less than the actual difference in the −2LL statistic between Models B and C, 46.24. Therefore, we judge the latter to be 'big,' and we reject the null and conclude that the interaction terms are needed, as a group. We prefer Model C to Model B, the proportionality assumption is violated, and the impact of *DEGREE* on logit-hazard is not identical in each time interval.
